Nets: 
Network Estimation for Time Series

Matteo Barigozzi‡  Christian Brownlees†

March 9, 2016

Abstract

We model a large panel of time series as a VAR where the autoregressive matrices and the inverse covariance matrix of the system innovations are assumed to be sparse. The system has a network representation in terms of a directed graph representing predictive Granger relations and an undirected graph representing contemporaneous partial correlations. A lasso algorithm called nets is introduced to estimate the model. We apply the methodology to analyse a panel of volatility measures of ninety bluechips. The model captures an important fraction of the overall variability of the time series and improves out–of–sample forecasting.

The procedures presented in this paper are available in the package nets for R.

We would like to thank Vasco Carvalho, Frank Diebold, Tony Hall, Nikolaus Hautsch, Julien Idier, Clifford Lam, Marco Lippi, Gabor Lugosi, Tommaso Proietti, and Kimmo Soramaki for their helpful comments. Special thanks go to Giorgio Calzolari. All mistakes are ours.
1 Introduction

Over the last years, network analysis has become an active topic of research in time series econometrics, with numerous applications in macroeconomics and finance. Example of contributions in the literature include, *inter alia*, Billio, Getmansky, Lo, and Pellizzon (2012), Diebold and Yilmaz (2014, 2015), Hautsch, Schaumburg, and Schienle (2014a,b) and Härdle, Wang, and Yu (2016). In a nutshell, network analysis is concerned with representing the interconnections of a large panel as a graph: the vertices of the graph represent the variables in the panel, and the presence of an edge between two vertices denotes the presence of some appropriate measure of dependence between the two variables. From an economic perspective, the interest on networks has been boosted by the research of, *inter alia*, Acemoglu, Carvalho, Ozdaglar, and Tahbaz-Salehi (2012), which shows that individual entities can have a non negligible effect on the aggregate economy when the system has a high degree of interconnectedness.

In this paper we propose network methodology for large panels of time series. We model the panel as a Vector Autoregression (VAR). We work under the assumption that the VAR is sparse, in the sense that the autoregressive matrices and the inverse covariance matrix of the system innovations are assumed to be sparse. Notice that the notion of sparsity used in this work is different from the one used in other papers such as Davis, Zang, and Zheng (2015), Kock and Callot (2015), and Medeiros and Mendes (2016) where sparsity assumptions are formulated for the autoregressive matrices only. Sparsity of the autoregressive matrices implies sparsity of the multivariate Granger causality structure of the system whereas sparsity of the inverse covariance matrix implies sparsity of the partial correlation structure (Dempster, 1972; Lauritzen, 1996).

Several network representations can be associated with a VAR system (Dahlhaus, 2000; Eichler, 2007; Diebold and Yilmaz, 2014). In this work we focus on two representations that are natural for the sparse VAR we work with. The first network representation consists of representing the system as a mixed graph containing both directed and undirected edges:
directed edges denote Granger causality linkages among time series while undirected edges represent contemporaneous partial correlation linkages. The second network representation we introduce is an undirected graph where edges denote long run partial correlation linkages among time series. Long run partial correlation is a partial correlation measure constructed on the basis of the long run covariance matrix of the VAR. It synthesises simultaneously lead/lag and contemporaneous dependence among time series and can be thought of as a natural generalization for dependent data of the standard partial correlation model used in the statistics graphical literature.

In order to estimate large sparse VARS, we introduce a novel LASSO-based algorithm. The highlight of the procedure is that it simultaneously estimates the autoregressive matrices as well as the entries of the concentration matrix, avoiding to split up the estimation of the model parameters in two steps. The large sample properties of the proposed estimator are analysed and we establish conditions for consistent selection and estimation of the VAR parameters. The theory is derived in a high-dimensional setting, allowing the number of series in the system to increase with the sample size. Specifically, the number of series is allowed to be $O(T^\zeta)$ for $\zeta > 0$ where $T$ denotes the sample size of the panel.

The network methodology we introduce in this work has highlights in terms of interpretation and estimation. Understanding and synthesising the interdependence structure of a large multivariate system can be a daunting task. The network representation of the panel provides a more parsimonious synthesis of the data that can bring useful insights on their underlying structure. From an estimation perspective, carrying out inference on the VAR parameters can be challenging when the number of time series is large. The regularized estimation approach based on LASSO put forward in this work can lead to substantial gains in terms of estimation precision when the system is sparse and, ultimately, forecasting.

A natural application of network analysis techniques is the study of interdependence in panels of volatility measures. Detecting the interconnectedness structure of volatility panels is of interest to understand and monitor the risk transmission channels of these systems. See,
for instance, the research of Diebold and Yılmaz (2014) on risk transmission in the 2007–2009
crisis. We use the methodology derived in this work to analyse a panel of volatility measures
for ninety US bluechips across different industry groups from January 2nd 2004 to December
31st 2015. An important feature of our application is that we study interconnectedness condi-
tional on a market wide and sector specific volatility factors. We show that after conditioning
on the factors the volatility panel has a sparse network structure capturing approximately
10% of the overall variability. The estimated networks connect the vast majority of the se-
ries in the panel and the interdependence is positive in the vast majority of cases. Results
show that the financial sector is the most interconnected industry in this sample period. In
particular, large financial institutions such as AIG, Bank of America and Citigroup are some
of the most interconnected entities in the panel. An out–of–sample forecasting exercise is
used to validate the methodology proposed in our work and shows that the sparse VAR model
improves predictive ability over a number of benchmarks.

Our work relates to different strands of literature. First, it is related to the econometric
literature on networks, which includes research by Billio et al. (2012), Diebold and Yilmaz
(2014, 2015), Hautsch et al. (2014a, b), Härdle et al. (2016). This paper is also related to
the literature on the estimation of sparse VARS, see Davis et al. (2015), Kock and Callot
(2015), Medeiros and Mendes (2016), and, in a Bayesian setting, Ahelegbey, Billio, and
Casarin (2015). Our contribution also relates to the statistical literature on large dimensional
network estimation based on LASSO techniques. Contributions in this area include, inter alia,
Meinshausen and Bühlmann (2006), Friedman, Hastie, and Tibshirani (2008), Peng, Wang,
Zhou, and Zhu (2009).

The paper is structured as follows. Section 2 introduces the model, the network def-
initions and the estimation strategy. Section 3 derives the large sample properties of the
estimator. Section 4 contains a simulation study that analyses the finite sample properties
of the procedure. Section 5 contains the empirical application. Concluding remarks follow
2 Methodology

2.1 Model

We consider a zero-mean stationary $n$-dimensional multivariate time series $y_t = (y_{1t}, \ldots, y_{nt})'$ generated by a $p$-th order VAR

$$y_t = \sum_{k=1}^{p} A_k y_{t-k} + \epsilon_t, \quad \epsilon_t \sim i.i.d. (0, C^{-1}),$$  

where $A_k$ and $C$ are $n \times n$ matrices. Throughout the VAR is assumed to be stable and $C$ to be positive definite. Notice that for convenience the distribution of the innovation terms is parametrized with the inverse covariance matrix $C$, also known as concentration matrix, rather than the covariance. The $(i,j)$-th entries of the matrices $A_k$ and $C$ are denoted respectively as $a_{kij}$ and $c_{ij}$.

In this work we focus on the analysis of sparse VAR systems, in the sense that the autoregressive matrices $A_k$ and the concentration matrix $C$ are assumed to be sparse matrices. More specific notions of sparsity are spelled out in Section 3 where precise assumptions are required by the estimation theory to establish the results of interest. In general, the sparsity assumption can be interpreted as a sparsity assumption on the lead/lag and contemporaneous dependence structure of the system.

The standard notion of dynamic interdependence used for time series is Granger causality. In this work we rely on a multivariate version of this concept. Formally, we say that $y_{jt}$ does not Granger cause $y_{it}$ if adding $y_{jt}$ as predictor does not improve the mean square forecast error of $y_{it+k}$ for any $k > 0$, that is

$$E[(y_{it+k} - E(y_{it+k} | \{y_{1t} \ldots y_{nt}\}))^2] = E[(y_{it+k} - E(y_{it+k} | \{y_{1t} \ldots y_{nt}\} \setminus y_{jt}))^2].$$  

(2)
It is immediate to see that the Granger causality structure of the model is encoded in the sparsity structure of the autoregressive matrices \( \mathbf{A}_k \). We have indeed that if \( a_{kij} = 0 \), for all \( k \), then \( y_{jt} \) does not Granger cause \( y_{it} \).

The classical measure of contemporaneous dependence used in the network literature is partial correlation. In this paper we consider partial correlation between two series conditional on the past realizations of the panel and contemporaneous realizations of the remaining series. This is encoded in the partial correlation between VAR innovations, which is defined as

\[
\rho_{ij} = \text{Cor}(\epsilon_{it}, \epsilon_{jt} | \{ \epsilon_{kt} : k \neq i, j \}).
\]  

(3)

It is well known that partial correlations are related to the entries \( c_{ij} \) of the concentration matrix \( \mathbf{C} \) by means of the relation (Dempster, 1972)

\[
\rho_{ij} = -\frac{c_{ij}}{\sqrt{c_{ii}c_{jj}}}.
\]  

(4)

Thus, the contemporaneous dependence sparsity structure is embedded in the sparsity structure of the concentration matrix \( \mathbf{C} \). Indeed, if \( c_{ij} = 0 \), then series \( i \) and \( j \) are contemporaneously uncorrelated conditional on all other series in the system.

Networks are a useful tool to represent the interdependence structure of the time series in the panel \( \mathbf{y}_t \). A network is defined as a graph \( \mathcal{N} = (\mathcal{V}, \mathcal{E}) \) where \( \mathcal{V} \) is the set of vertices and \( \mathcal{E} \) is the set of edges. The set of vertices \( \mathcal{V} \) is \( \{1, ..., n\} \) where each element corresponds to a component of \( \mathbf{y}_t \), while the set of edges \( \mathcal{E} \) is a subset of \( \mathcal{V} \times \mathcal{V} \) such that the pair \( (i, j) \) is in \( \mathcal{E} \) if and only if the components \( i \) and \( j \) are linked by an edge.

Several network definitions have been proposed for VAR models. In this work we introduce two network definitions that are natural for the sparse VAR model we focus on.

A natural representation of the sparse VAR model we work with in this paper is based on the union of two graphs: the first graph contains directed edges denoting Granger causality linkages among time series, while the second graph contains undirected edges representing...
contemporaneous partial correlation linkages. We label the two networks respectively as the Granger and contemporaneous networks. The Granger network is defined as a directed network \( N_G = (\mathcal{V}, \mathcal{E}_G) \) where the presence of an edge from \( i \) to \( j \) denotes that \( i \) Granger causes \( j \) in the sense of (2), that is

\[
\mathcal{E}_G = \{(i, j) \in \mathcal{V} \times \mathcal{V} : a_{kij} \neq 0, \text{ for at least one } k \in \{1, \ldots, p\}\}.
\]  

(5)

The contemporaneous network is defined as an undirected network \( N_C = (\mathcal{V}, \mathcal{E}_C) \) where an edge between \( i \) and \( j \) denotes that \( i \) is partially correlated to \( j \), that is

\[
\mathcal{E}_C = \{(i, j) \in \mathcal{V} \times \mathcal{V} : \rho^{ij} \neq 0\}.
\]  

(6)

An alternative way to represent the properties of the process consists of simultaneously summarising the lead/lag and contemporaneous information of the system by introducing a partial correlation measure based on the long run covariance matrix of the process. This idea is inspired by the HAC literature (see Newey and West, 1987; Andrews and Monahan, 1992; Den Haan and Levin, 1996). The long run covariance matrix of the process \( y_t \) can be defined as the covariance of the aggregated process:

\[
\Sigma_L = \lim_{M \to \infty} \frac{1}{M} \text{Cov} \left( \sum_{t=1}^{M} y_t, \sum_{t=1}^{M} y_t \right),
\]

assuming the limit exists. Equivalently, the long run covariance is defined in terms of the sum of all autocovariance functions of the process, that is the zero frequency spectral density matrix, which is given by

\[
\Sigma_L = \sum_{h=-\infty}^{+\infty} \text{E}[y_t y_{t-h}^\prime],
\]

which shows how \( \Sigma_L \) synthesises the linear dependences of \( y_t \) at every lead and lag. Note that since the VAR is assumed to be stationary the sum above is well defined. As it is well
known, in the case of a VAR model the long run covariance is given by

$$\Sigma_L = \left( I - \sum_{k=1}^{p} A_k \right)^{-1} C \left( I - \sum_{k=1}^{p} A_k' \right)^{-1}.$$

We propose a network definition based on the partial correlations constructed on the basis of the long run concentration matrix which is defined as

$$K_L = \Sigma_L^{-1} = \left( I - \sum_{k=1}^{p} A_k \right)' C \left( I - \sum_{k=1}^{p} A_k \right).$$

This is also known as the zero-frequency partial spectral coherence (Dahlhaus, 2000; Davis et al., 2015). Notice that the expression of $K_L$ is factorized in a sandwich form determined by the term $I - \sum_{k=1}^{p} A_k$, which captures long run dynamic relations of the system, and the term $C$, which accounts for the contemporaneous dependence of the system innovations. We can then express long run partial correlation coefficient for series $i$ and $j$ as a function of the entries $k_{Lij}$ of the long run concentration matrix $K_L$

$$\rho_{ij}^L = -\frac{k_{Lij}}{\sqrt{k_{Lii}k_{Ljj}}}.$$  

The long run partial correlation network is then defined as a undirected network $N_L = (\mathcal{V}, \mathcal{E}_L)$ where the set of edges $\mathcal{E}_L$ is defined as

$$\mathcal{E}_L = \left\{ (i, j) \in \mathcal{V} \times \mathcal{V} : \rho_{ij}^L \neq 0 \right\}. \quad (7)$$

A number of comments on the model and network definitions we propose are in order. First, this work assumes that the panel has a sparse dependence structure. In practice, this assumption can be quite restrictive. An important case in which the assumption of sparsity is violated, is when the components of the panel are a function of a set of common factors (Forni, Hallin, Lippi, and Reichlin, 2000; Stock and Watson, 2002a,b; Bai, 2003). It is
straightforward to see that common factors induce a fully interconnected network structure among the variables in the panel. In these cases the influence of the common factors ought to be filtered out before carrying out network analysis. Generally speaking, we view network analysis as a complement of factor analysis for the purpose of empirical applications (see for example the empirical results in De Mol, Giannone, and Reichlin, 2008 for a justification of this approach).

An important difference between the network modelling approached proposed here and other contributions in the literature is that we focus on representing the partial dependence structure of the panel. On the other hand, the contributions of, inter alia, Billio et al. (2012) and Diebold and Yılmaz (2014) propose network definitions that measure the overall degree of dependence between series. The advantage of the approach proposed here is that it is robust to spurious correlation effects among the variables in the system. Moreover, the network definitions we propose can be seen as natural extension for time series data of the popular partial correlation network models used in statistics.

2.2 Estimation

We are interested in detecting and estimating the non–zero entries of the autoregressive matrices $A_k$ and the concentration matrix $C$. A simple estimation approach for the sparse VAR would consist of using LASSO regression to estimate the autoregressive matrices $A_k$ (as for example in Kock and Callot, 2015), and then using a LASSO procedure on the residuals to estimate the concentration matrix $C$ (as for example in Friedman et al. 2008; Peng et al., 2009). The analysis of properties of the second step estimator is however challenging. Moreover, the rate of convergence of the estimator of the concentration matrix $C$ would

\[ y_{it} = \beta_i f_t + \epsilon_{it}, \]

where $f_t$ and $\epsilon_{it}$ are independent normals with zero mean and unit variance and $\epsilon_{it}$ and $\epsilon_{jt}$ are independent for each $i \neq j$. Then the concentration matrix of the system is $K = I_n - \frac{\beta \beta'}{\bar{y} \beta}$, where $I_n$ is the identity matrix of size $n \times n$ and $\beta$ is a $n \times 1$ vector of factor loadings $\beta_i$. If the vector of factor loading does not contain zero entries then $K$ is not sparse.

\[ 1 \]

Consider an $n$–dimensional panel of time series $y_{it}$ generated by a one factor model
depend on the rate of convergence of the estimator of the autoregressive matrices $A_k$. In this work we propose an estimation approach that avoids these hurdles by estimating both sets of parameters jointly.

For ease of notation, we re-parametrize the VAR as a function of: (i) the coefficients $\alpha_{ijk}$ contained in an $n^2p$-dimensional vector $\alpha$ which correspond to the autoregressive coefficients $a_{kij}$ in (1), (ii) the partial correlations $\rho^{ij}$ contained in an $n(n-1)/2$-dimensional vector $\rho$ and defined in (3), and (iii) the coefficients $c_{ii}$ contained in an $n$-dimensional vector $c$ which correspond to the diagonal of the concentration matrix $C$. Then, in scalar notation the parameters of our model are given by the VAR equations

$$y_{it} = \sum_{k=1}^{p} \sum_{j=1}^{n} \alpha_{ijk} y_{jt-k} + \epsilon_{it}, \quad i = 1, \ldots, n,$$

and the contemporaneous equations (see [Peng et al., 2009])

$$\epsilon_{it} = \sum_{h=1}^{n} \rho^{ih} \sqrt{\frac{c_{hh}}{c_{ii}}} \epsilon_{ht} + u_{it}, \quad i = 1, \ldots, n,$$

where $u_{it}$ is an error term uncorrelated with $\epsilon_{ht}$ for $i \neq h$.

In this section we define a novel LASSO based estimator for the parameters of (8) and (9). We call the estimation algorithm nets (Network Estimator for Time Series) and we describe it in detail in the next section. The main feature of the proposed procedure is that it estimates the autoregressive parameters, $\alpha$, and partial correlations, $\rho$, simultaneously, conditional on a pilot estimator of $c$.

Consider the following regression representation of $y_{it}$ as a function of the lags of all series as well as the contemporaneous realizations of all other series in the panel, that is

$$y_{it} = \sum_{k=1}^{p} \sum_{j=1}^{n} \beta_{ijk} y_{jt-k} + \sum_{h=1}^{n} \gamma_{ih} y_{ht} + \epsilon_{it},$$

\(^2\)This is shown in a previous working paper version of this manuscript.
where $e_{it}$ is an error term. It is straightforward to see that (see Lemma 1) the $\beta_{ijk}$ and $\gamma_{ih}$ coefficients can be expressed as a function of the $\alpha_{ijk}$, $\rho^i$ and $c_{ii}$ parameters. In particular, (10) can be re-written as

$$y_{it} = \sum_{k=1}^{p} \sum_{j=1}^{n} \left( \alpha_{ijk} - \sum_{l=1 \atop l \neq i}^{n} \rho^l \sqrt{c_{li}} \alpha_{ljk} \right) y_{jt-k} + \sum_{h=1 \atop h \neq i}^{n} \rho^h \sqrt{c_{hi}} \gamma_{h} y_{ht} + u_{it}. \quad (11)$$

Notice that the lemma shows that the errors $e_{it}$ and $u_{it}$ are the same. We denote by $\theta$ the vector of parameters of interest $(\alpha', \rho')'$ of dimension $m = n^2p + n(n-1)/2$. The regression representation in (11) suggests to associate the following quadratic loss function to the problem of determining $\theta$, conditional on $c$,

$$\ell(\theta; y_t, c) = \sum_{i=1}^{n} \left( y_{it} - \sum_{k=1}^{p} \sum_{j=1}^{n} \left( \alpha_{ijk} - \sum_{l=1 \atop l \neq i}^{n} \rho^l \sqrt{c_{li}} \alpha_{ljk} \right) y_{jt-k} - \sum_{h=1 \atop h \neq i}^{n} \rho^h \sqrt{c_{hi}} \gamma_{h} y_{ht} \right)^2. \quad (12)$$

If a sample of $T$ observations of the $y_t$ process is available for $t = 1, \ldots, T$ then we propose to estimate the model parameters using a LASSO–type estimator

$$\hat{\theta}_T = \arg \min_{\theta \in \mathbb{R}^m} \left[ \frac{1}{T} \sum_{t=1}^{T} \ell(\theta; y_t, \hat{c}_T) + \lambda^G_T \sum_{k=1}^{p} \sum_{i,j=1}^{n} \frac{|\alpha_{ijk}|}{\tilde{\alpha}_{ijk}} + \lambda^C_T \sum_{l,h=1 \atop l \neq h}^{n} \frac{|\rho^h|}{\tilde{\rho}_{lh}} \right], \quad (13)$$

where $\lambda^G_T > 0$ and $\lambda^C_T > 0$ are the LASSO tuning parameters and $\tilde{\alpha}_T$, $\tilde{\rho}_T$ and $\hat{c}_T$ are pre–estimators of the $\alpha$, $\rho$, and $c$ coefficients, respectively. Due to the presence of autocorrelation in and across the components of $y_t$ the regressors in (11) are likely to be dependent, therefore we adopt here an adaptive LASSO penalty as originally proposed by Zou (2006) and then studied by Kock (2012, 2016) for dependent data. If the sample size is sufficiently large, a natural pre–estimator of $\alpha$ is the least squares estimator of the VAR autoregressive matrices while the pre–estimator of $\rho$ is the partial correlation estimator obtained from the sample
covariance of the VAR residuals. Otherwise, if the sample size is not sufficiently large a pre–estimator of \( \alpha \) could be obtained by estimating the autoregressive matrices via ridge regression while the pre–estimator of \( \rho \) could be obtained from a shrinkage estimator of the residual covariance (Ledoit and Wolf 2004). Last, a possible choice for the pre–estimator of \( c \) is the reciprocal of the variance of each series (Peng et al. 2009).

### 2.3 The nets algorithm

In this section we introduce the nets algorithm to solve the optimization problem of equation (13). Notice that the loss function in (12) is not the standard quadratic loss function of a linear regression model and the standard LASSO algorithms cannot be applied. However, it is still possible to design a coordinate descent algorithm that can be used to minimize the objective function of (13). The procedure we propose is a generalization of the space algorithm proposed by Peng et al. (2009) for the estimation of partial correlation networks, and its a variation of the shooting algorithm of Fu (1998) typically used for LASSO optimization.

Additional notation is required to describe the algorithm. We begin by introducing the matrix representation of the model of equation (11) obtained by stacking the time series in the panel. Let \( \mathbf{Y} \) denote a \( nT \times 1 \) vector defined as \( (y_{11}, ..., y_{1T}, ..., y_{i1}, ..., y_{iT}, ..., y_{n1}, ..., y_{nT})' \); let \( \mathbf{X}_G = (x_{G111}, ..., x_{Gijk}, ..., x_{Gnmp}) \) be a \( nT \times n^2p \) matrix with \((i,j,k)\)-th column defined as

\[
x_{Gijk} = (0, ..., 0, y_{j-k}, ..., y_{it-k}, ..., y_{jT-k}, 0, ..., 0)',
\]

and let \( \mathbf{X}_C = (x_{C21}, x_{C31}, x_{C32}, ..., x_{Cij}, ..., x_{Cn(n-1)}) \) be a \( nT \times n(n - 1)/2 \) matrix with \((i,j)\)-th column defined as

\[
x_{Cij} = \left(0, ..., 0, \sqrt{\frac{c_{jj}}{c_{ii}}} (y_{j1}, ..., y_{jt}, ..., y_{jT}) 0, ..., 0, \sqrt{\frac{c_{ii}}{c_{jj}}} (y_{i1}, ..., y_{it}, ..., y_{iT}) 0, ..., 0 \right)',
\]
Then, it is straightforward to check that model (11) can be represented as

\[ \mathbf{Y} = \mathbf{X}_G \mathbf{\beta}(\mathbf{\alpha}, \mathbf{\rho}) + \mathbf{X}_C \mathbf{\rho} + \mathbf{U}, \]

where \( \mathbf{U} \) is a \( nT \times 1 \) vector of residuals and \( \mathbf{\beta}(:, :) \) denotes the function which maps the \( \mathbf{\alpha} \) and \( \mathbf{\rho} \) parameter vectors onto the \( \mathbf{\beta} \) parameter vector whose components are given in (10). Notice that the parameter \( \mathbf{\beta} \) and the matrix \( \mathbf{X}_C \) depend implicitly on the parameter \( \mathbf{c} \) and that in the estimation we set this to the pre-estimator \( \hat{\mathbf{c}}_T \). The dependence on \( \mathbf{c} \) is suppressed in the notation for simplicity. In what follows it is convenient to introduce shorthand notation for the stacked vectors. Let \( \mathbf{v} \) be a \( nT \times 1 \) stacked vector, then we use \( \mathbf{v}_{[it]} \) to refer to the \( t \)-th element of the \( i \)-th block of \( \mathbf{v} \).

The nets algorithm is an iterative coordinate descent procedure for the minimization of the objective function of (13). Each iteration \( s \) of the algorithm updates one component of the parameter vector \( \mathbf{\theta} = (\mathbf{\alpha}', \mathbf{\rho}')' \). The \( \mathbf{\alpha} \) and \( \mathbf{\rho} \) parameter estimates at iteration \( s \) are denoted as \( \hat{\mathbf{\alpha}}^{(s)} \) and \( \hat{\mathbf{\rho}}^{(s)} \) respectively. We define the residual estimate at iteration \( s \) as

\[ \hat{\mathbf{U}}^{(s)} = \mathbf{Y} - \mathbf{X}_G \mathbf{\beta}(\hat{\mathbf{\alpha}}^{(s)}, \hat{\mathbf{\rho}}^{(s)}) - \mathbf{X}_C \hat{\mathbf{\rho}}^{(s)}. \]

The algorithm iterates until convergence, which is checked at the end of each full cycle of updates of \( \mathbf{\theta} \). To describe the algorithm, it is useful to use two auxiliary \( nT \times 1 \) stacked vectors \( \mathbf{\tilde{x}} \) and \( \mathbf{\tilde{y}} \). The \( \mathbf{\tilde{x}} \) vector denotes the regressors corresponding to the current coefficient being updated, while the \( \mathbf{\tilde{y}} \) vector is the partial residual of the model with respect to all parameter besides the coefficient being currently updated (either \( \alpha_{ijk} \) or \( \rho_{ij} \)). The \( \alpha_{ijk} \) coefficient is updated as

\[ \hat{\alpha}^{(s)}_{ijk} = \text{sign} \left( \mathbf{\tilde{y}}' \mathbf{\tilde{x}} \right) \left( \frac{\mathbf{\tilde{y}}' \mathbf{\tilde{x}}}{\mathbf{\tilde{x}}' \mathbf{\tilde{x}}} - \frac{\lambda G \mathbf{1}}{\hat{\alpha}^{(s)}_{ijk} \mathbf{\tilde{x}}' \mathbf{\tilde{x}}} \right)_+, \]
where $\tilde{x}$ and $\tilde{y}$ are defined as

$$
\tilde{x}_{[lt]} = \begin{cases} 
y_{lt-k}, & \text{if } l = i \\
-\hat{\rho}^{il}(s-1) \sqrt{\hat{c}_{ii}} y_{jt-k} & \text{otherwise}
\end{cases}
\tilde{y}_{[lt]} = \mathcal{U}_{[lt]}^{(s-1)} + \hat{\alpha}_{ij}^{(s-1)} \tilde{x}_{[lt]},
$$

for each $l = 1, \ldots, n$ and $t = 1, \ldots, T$. The $\hat{\rho}^{ij}$ coefficient is updated as

$$
\hat{\rho}^{ij}(s) = \text{sign} \left( \tilde{y}' \tilde{x} \right) \left( \frac{\tilde{y}' \tilde{x}}{\tilde{x}' \tilde{x}} \right) - \frac{\lambda c}{\hat{\rho}^{ij} \tilde{x}' \tilde{x}},
$$

where $\tilde{x}$ and $\tilde{y}$ are defined as

$$
\tilde{x}_{[lt]} = \sqrt{\hat{c}_{hh}} \left( y_{ht} - \sum_{j=1}^{n} \sum_{k=1}^{p} \alpha_{hjk}^{(s-1)} y_{jt-k} \right)
\tilde{y}_{[lt]} = \mathcal{U}_{[lt]}^{(s-1)} + \hat{\rho}^{ij}(s-1) \tilde{x}_{[lt]},
$$

for $(l, h)$ equal $(i, j)$ or $(j, i)$ and $t = 1, \ldots, T$, and otherwise $\tilde{y}_{[lt]}$ and $\tilde{x}_{[lt]}$ are set to zero.

It is important to stress that the parameter vector $\theta$ contains $n^2 p + \frac{n(n-1)}{2}$ elements, whose optimization would require large amounts of memory to be stored when the panel is large. On the other hand, the coordinate wise minimization algorithm is appealing in this context in that it has mild storage requirements and can be applied in large dimensional applications.

As far as the estimation of $\mathbf{c}$ is concerned, we follow the two-step iterative procedure proposed in [Peng et al. (2009)]: (i) Given an estimate of $\mathbf{c}$, we estimate the $\theta$ parameter using nets. (ii) Given an estimate $\mathbf{c}$ and an estimate of $\theta$ we update the estimate of $\mathbf{c}$. Notice, that $c_{ii}$ is the reciprocal of the residual variance of equation (11). These two steps are then iterated until convergence, which typically kicks in within very few iterations.

A number of hacks have been developed in the literature to optimize the estimation of lasso models when the number of parameters is large. We point out here that the active shooting approach proposed in [Peng et al. (2009)] is particularly useful. Active shooting
consists of carrying out the coordinate descent steps for the current non–zero parameters until convergence (the active set) and then for the zero parameters. When the LASSO solution is sparse, active shooting can lead to substantial advantages in terms of execution time.

3 Theory

In this section we show, under appropriate conditions, the estimation and selection consistency of the estimator defined in the previous section. We denote by $\theta_0 = (\alpha'_0, \rho'_0)'$ and $c_0$ the true value of the parameters $\theta = (\alpha', \rho')'$ and $c$. The proofs of the propositions of this section are provided in the Appendix.

The detailed assumptions are given in the Appendix and here we only review the main features of the model. First, we assume $y_t$ to be generated by a stable VAR as in (1). Moreover, we require bounds on the higher order moments of $y_t$, such that suitable Bernstein-type exponential inequalities for dependent processes apply (see e.g. Bosq, 1996; Doukhan and Neumann, 2007). Second, we assume positive definiteness of the spectral density matrix of $y_t$ and of the precision matrix, $C_0$, of the VAR innovations $\epsilon_t$. This guarantees that the population Granger and contemporaneous network are both well defined. Given the loss function, $\ell(\theta; y_t, c)$ defined in (12), the unconstrained problem has a solution in population, i.e. the parameter vector $\theta_0$ is identified.

**Proposition 1.** Under Assumption [1] the true value of the parameters is such that $\theta_0 = \arg \min_{\theta} \mathbb{E}[\ell(\theta; y_t, c_0)]$.

The estimator defined in (13) can be equivalently formulated as

$$\hat{\theta}_T = \arg \min_{\theta \in \mathbb{R}^m} \mathcal{L}_T(\theta, \hat{c}_T),$$

(14)

where

$$\mathcal{L}_T(\theta, \hat{c}_T) = \left[ \frac{1}{T} \sum_{t=1}^{T} \ell(\theta; y_t, \hat{c}_T) + \lambda_T \sum_{i=1}^{m} w_i |\theta_i| \right],$$

(15)
where $\lambda_T$ is the LASSO tuning parameter and $w_i$ are the adaptive LASSO weights. The specification of the weight is $w_i = C_*/|\tilde{\theta}_{Ti}|$ where $\tilde{\theta}_{Ti}$ denotes the pre-estimator of the $\theta_i$ coefficient and $C_*$ denotes a known positive constant that is equal to $C_\alpha$ for the $\alpha$ coefficients and $C_\rho$ for the $\rho$ coefficients. Put differently, in the theoretical analysis of the estimator we assume that the $\lambda^G_T = \lambda_T C_\alpha$ and $\lambda^C_T = \lambda_T C_\rho$. Thus, $\lambda_T$ controls the overall degree of shrinkage of the parameters of the model.

In what follows we denote the sets of non-zero parameters as $A_G = \{(i,j,k) : \alpha_{0ijk} \neq 0\}$, $A_C = \{(i,j) : \rho_{ij} \neq 0\}$ and $A = A_G \cup A_C$. The number of non-zero parameters in the model is $q_T = |A|$. The set of zero parameters is then $A^c$. Let also $\{s_T\}$ be a positive sequence of real numbers such that for any $i \in A$ we have $|\theta_{0i}| \geq s_T$.

The solution of (14) when restricted to the set of parameters $\theta$ such that $\theta_{Ac} = 0$ is denoted as $\hat{\theta}_T^A$. This is the estimator of the non-zero parameters obtained when we assume to know those that are zero. To obtain consistency we follow the same strategy as in Meinshausen and Bühlmann (2006), Peng et al. (2009), and Fan and Peng (2004). First, we prove consistency in the restricted problem.

**Proposition 2. (estimation consistency).** Suppose that, as $T \to \infty$, $q_T = o\left(\sqrt{\frac{T}{\log T}}\right)$, $\lambda_T \sqrt{\frac{T}{\log T}} \to \infty$, and $\sqrt{q_T \lambda_T} = o(1)$. Then, under Assumptions 1 and 2, for any $\eta > 0$, $\hat{\theta}_T^A$ exists with probability at least $1 - O(T^{-\eta})$, and there exists a constant $\kappa_R > 0$ such that

$$\Pr\left(\|\hat{\theta}_T^A - \theta_{0A}\| \leq \kappa_R \sqrt{q_T \lambda_T}\right) \geq 1 - O(T^{-\eta}).$$

Moreover, if the signal sequence $s_T$ is such that, $\frac{s_T}{\sqrt{q_T \lambda_T}} \to \infty$, then $\Pr\left(\text{sign}(\hat{\theta}_{Ti}^A) = \text{sign}(\theta_{0i})\right) \geq 1 - O(T^{-\eta})$, for any $i \in A$.

Second, we show that the restricted estimator is also a solution of the unrestricted problem, i.e. when we do not know the zero coefficients (see Lemma 8 in the Appendix). Then, in the next Proposition, we prove consistency of edge selection and of the unrestricted estimator.
Proposition 3. (selection consistency and oracle property). Suppose that the same conditions of Proposition 2 hold and that, as $T \to \infty$, $n = O(T^\zeta)$ for some $\zeta > 0$ and $\sqrt{T} \frac{\log T}{T} = o(\lambda_T)$. Then, under Assumptions 1 and 2, for any $\eta > 0$, $\hat{\theta}_T$ exists with probability at least $1 - O(T^{-\eta})$. Moreover,

(a) $\Pr(\hat{\theta}_{T,i} = 0) \geq 1 - O(T^{-\eta})$, for any $i \in \mathcal{A}^c$;
(b) there exists a constant $\kappa_U > 0$ such that

$$\Pr\left(\|\hat{\theta}_T - \theta_0\| \leq \kappa_U \sqrt{T} \lambda_T\right) \geq 1 - O(T^{-\eta}),$$

and $\Pr(\text{sign}(\hat{\theta}_{T,i}) = \text{sign}(\theta_{0,i})) \geq 1 - O(T^{-\eta})$, for any $i \in \mathcal{A}$.

Since $\hat{\theta}_T = (\hat{\alpha}_T, \hat{\rho}_T)'$, as an immediate consequence of Proposition 3, we have consistency of all the estimated parameters of the model and we have selection consistency for the non–zero edges of the Granger and contemporaneous networks.

Corollary 1. Define as $\hat{\alpha}_{T,ijk}$ the generic entry of $\hat{\alpha}_T$ and as $\hat{\rho}_{ij}^{T}$ the generic entry of $\hat{\rho}_T$, and define the estimated edges’ sets of the Granger and contemporaneous networks as

$$\hat{\mathcal{E}}_G = \{(i,j) \in \mathcal{V} \times \mathcal{V} : \hat{\alpha}_{T,ijk} \neq 0, \text{ for at least one } k \in \{1,\ldots,p\}\} ,$$

$$\hat{\mathcal{E}}_C = \{(i,j) \in \mathcal{V} \times \mathcal{V} : \hat{\rho}_{ij}^{T} \neq 0\} .$$

Then, under the same Assumptions of Proposition 3, for $T$ sufficiently large and any $\eta > 0$, we have $\Pr(\hat{\mathcal{E}}_G = \mathcal{E}_G) \geq 1 - O(T^{-\eta})$, and $\Pr(\hat{\mathcal{E}}_C = \mathcal{E}_C) \geq 1 - O(T^{-\eta})$.

Given the asymptotic conditions on the number of non–zero coefficients, $q_T$, the “worst case” scenario is when it is almost in the order of $\sqrt{\frac{T}{\log T}}$. In that case $\lambda_T$ needs to be nearly in the order of $T^{-1/4}$. On the other hand, for the “best case” scenario, that is when $q_T = O(1)$ (for example, when the dimension $n$ is fixed), then the order of $\lambda_T$ can be nearly as small as $T^{-1/2}$ (within a factor of $\log T$). Consequently, the $L_2$-norm distance of the estimator from the true parameter is in the order of $\sqrt{\frac{\log T}{T}}$, with probability at least $1 - O(T^{-\eta})$. 

17
4 Simulation Study

In this section we analyse the properties of our estimator using simulated data. The exercise consists of simulating a large sparse VAR process and then using the nets algorithm to estimate it.

We simulate a 100 dimensional sparse VAR(1). Notice that the total number of parameters in this system is 15050. The sparse autoregressive matrix $A_1$ and concentration matrix $C$ are obtained from an Erdős–Renyi random graph model. The Erdős–Renyi random graph is a graph defined over a fixed set of vertices and a random set of edges, where the existence of an edge between vertices $i$ and $j$ is determined by a Bernoulli trial with probability $p$, independent of all other edges. The $A_1$ matrix is constructed on the basis of a directed Erdős–Renyi model $G_1$

$$[A_1]_{ij} = \begin{cases} 
0.275 & \text{if } (i, j) \in E_1 \\
0 & \text{otherwise}
\end{cases},$$

where $E_1$ is the set of (directed) edges of $G_1$. The concentration matrix $C$ is constructed on the basis of a undirected Erdős–Renyi model $G_2$

$$[C]_{ij} = \begin{cases} 
-\frac{1}{\sqrt{d_id_j}} & \text{if } i \neq j \text{ and } (i, j) \in E_2 \\
1.5 & \text{if } i = j \\
0 & \text{otherwise}
\end{cases},$$

where $E_2$ is the set of (undirected) edges of $G_2$ and $d_i$ denotes the degree of vertex $i$ in this graph. Note that the simulation is designed in a way such that the sparsity structure of the Granger and contemporaneous networks of the VAR coincide with the one of the two random graphs $G_1$ and $G_2$. Also, the specification guarantees that the VAR is stable and that the concentration matrix is positive definite. The edge probability $p$ is set so that the expected
number of links in each of the two networks is equal to the number of series, \( n \), in the panel. We report in Figure 1 the plot of the Granger and contemporaneous networks associated with a randomly chosen realization of the model. Notice that despite the networks being sparse (in the sense that the expected number of links is \( O(n) \)), they are almost fully interconnected. We simulate samples of different sizes from the sparse \( \text{var}(1) \) we just described (\( T = 250, 500, 750 \) and 1000) and then use the \text{nets} algorithm to estimate the model. For simplicity, the tuning parameters \( \lambda^G_T \) and \( \lambda^C_T \) are set equal to a common shrinkage tuning parameter \( \lambda_T \). Our LASSO estimator requires pre–estimators of the \( \alpha \) and \( \rho \) parameters to construct the LASSO penalty weights. The pre–estimator of \( \alpha \) is the least squares estimator of the \( \text{var}(1) \) autoregressive matrix, while the pre–estimator of \( \rho \) is the partial correlation estimator obtained from the sample covariance of the \( \text{var}(1) \) residuals. Last, we initialize \( c \) using the reciprocal of the sample variances of each series. The model is then estimated over a range of values of the common shrinkage tuning parameter \( \lambda_T \).

**FIGURE 2 AND TABLE 1 ABOUT HERE**

The simulation is replicated 1000 times and the quality of the \text{nets} estimator is measured on the basis of the MSE and the ROC curve, which is the plot of the false discovery rate (FDR) of the estimator versus the true positive rate (TPR). We report in the left panel of Figure 2 the MSE of the \text{nets} estimator as a function of the tuning parameter \( \lambda_T \) for the sample size \( T \) equal to 500, 750 and 1000.\(^3\) The picture displays the typical profile of shrinkage type estimators, that is the MSE is a convex function of the tuning parameter, and as the sample size increases the MSE of the estimator decreases. The right panel of Figure 2 reports the ROC curve associated with the \text{nets} estimator for the sample size \( T \) equal to 250, 500, 750 and 1000. Recall that the FDR is defined as the ratio of incorrectly detected non–zero parameters over the total number of zero parameters, while TPR is defined as the ratio of correctly detected non–zero parameters over the total number of non–zero parameters. Note that the penalization coefficient determines the FDR and TFR properties of the estimator:

\(^3\)We omit from the picture for \( T = 250 \) because of scaling issues.
when $\lambda_T$ is small (large), the proportion of type 1 errors is high (low) while the proportion of type 2 errors is low (high). The curves show that as the sample size $T$ increases the performance of the nets estimator, as measured by the area underneath the ROC curve, increases steadily. In Table 1 we report detailed results on the MSE and TPR of the nets estimator when the FDR is controlled at 1%, 5% and 10%. For comparison purposes, the table also reports the MSE of the pre–estimator. The MSE of the nets estimator decreases steadily as the sample size get larger. When the sample size is 250 the efficiency gains with respect to the pre–estimator are substantial. As the sample size increases the pre–estimator becomes progressively more efficient relative to the LASSO estimator, however the efficiency gain of nets are still large. As far as the TPR is concerned, the table shows that when the TPR is controlled at 1%, 5% and 10% levels, the procedure has a fair amount of power even when the sample size $T$ is 250, and that as the sample size increases power raises steadily. In particular, the power is roughly around 80% when the sample size is 750 and the FDR is controlled at the 1% level. Overall, the simulation results convey that the nets algorithm performs satisfactorily, and that the gains with respect to the traditional estimator can be large for sparse VAR systems.

5 Empirical Application

We use the methodology introduced in this work to study interconnectedness in a panel of volatility measures. The application is close in spirit to, among others, the research of Diebold and Yilmaz (2009, 2014, 2015) and Engle et al. (2012).

5.1 Data

We consider a panel of ninety U.S. bluechips across different industry sectors. The list of company names and industry groups is in Table 2. Our sample spans January 2nd 2004
to December 31st 2015, which corresponds to 3021 trading days. During this sample period most of the stocks in the list have been part of the S&P 100 index. Following [Diebold and Yılmaz (2015)] we measure volatility using the high–low range (Parkinson, 1980)

$$\tilde{\sigma}_{it}^2 = 0.361 \left( p_{it}^{\text{high}} - p_{it}^{\text{low}} \right),$$

where $p_{it}^{\text{high}}$ and $p_{it}^{\text{low}}$ denote respectively the max and the min log price of stock $i$ on day $t$.

We focus on analyzing volatility interconnectedness conditional on a market wide and sector specific volatility factors. There is a large literature documenting evidence of a factor structure in volatility (see, *inter alia*, Barigozzi, Brownlees, Gallo, and Veredas, 2014; Luciani and Veredas, 2015; Ghysels, 2014; Barigozzi and Hallin, 2015). As previously pointed out, it is straightforward to check that when common factors are present the dependence structure of the data is not sparse. To this extent, we study the interconnectedness of the residuals of the regression

$$\log \tilde{\sigma}_{it}^2 = \beta_0 + \beta_1 \log \tilde{\sigma}_{m,t}^2 + \beta_2 \log \tilde{\sigma}_{s,t}^2 + z_{it},$$

(16)

where $\tilde{\sigma}_{m,t}^2$ and $\tilde{\sigma}_{s,t}^2$ denote respectively a market wide and a sector specific volatility factors. The market and sectoral volatilities are measured using the high–low range estimator applied to the S&P 500 index and the SPDR sectoral indices of S&P 500. The residuals are obtained after estimating the model by least squares. In what follows we refer to the volatility residual panel as the volatility panel for short.

---

4 Several advanced estimators of volatility based on high frequency data have been proposed over the last years (Andersen, Bollerslev, Diebold, and Labys 2003; Barndorff-Nielsen, Hansen, Lunde, and Shephard 2008; Ait-Sahalia, Mykland, and Zhang 2005). However, despite its simplicity a number of contributions have pointed out that the high–low range estimator performs satisfactorily relative to more sophisticated alternatives (Alizadeh, Brandt, and Diebold 2002, Brownlees and Gallo 2010).

5 The SPDR sectoral indices of the S&P 500 we use are Consumer Discretionary (XLY), Consumer Staples (XLP), Energy (XLE), Financials (XLF), Health Care (XLV), Industrials (XLI), Materials (XLB), Technology (XLK) and Utilities (XLU).
Table 3 reports summary statistics on the variance, kurtosis, autocorrelation, average cross correlation and average cross autocorrelation of order one for the volatility residuals. Moreover, in Figure 3 we show the heatmaps of the sample autocorrelation matrix of order one and the sample correlation matrix. We note that after netting out the factors, the volatility residuals still exhibit autocorrelation. It is important to emphasize that while the raw volatility measure exhibit long range dependence, the volatility residuals exhibit a considerably weaker autocorrelation structure. Inspection of the average correlations and the heatmaps shows that contemporaneous and lagged cross correlation is still present in the volatility residuals. Interestingly, tickers in the same industry still exhibit a moderate degree of correlation even after conditioning on the sectoral factors.

5.2 In–Sample Estimation Results

We analyse the panel of volatility measures using the nets algorithm over the entire sample. The order of the \( \text{VAR} \) model \( p \) is set to one. The pre–estimator of the \( \alpha \) parameters is the least squares estimator of the \( \text{VAR}(1) \) autoregressive matrix, while the pre–estimator of the \( \rho \) parameters is the partial correlation estimator obtained from the sample covariance of the \( \text{VAR}(1) \) residuals. Last, we initialize \( c \) using the reciprocal of the sample variances of each series. The penalties \( \lambda^G_T \) and \( \lambda^C_T \) are determined by a cross–validation procedure. We split the entire sample in an estimation and a validation samples. The estimation sample corresponds to the first 75% of the entire sample and the validation sample to the last 25%. For given values of the tuning parameters, we first estimate the model in the estimation sample and then compute the residual sum of squares (RSS) in the validation sample. We perform these steps over a grid of \( \lambda^G_T \) and \( \lambda^C_T \) values and then choose the optimal tuning parameters as the ones that minimize the validation RSS. We then estimate the model over the entire sample using the optimal value of the tuning parameters.

TABLE 4 AND FIGURE 4 ABOUT HERE
We report the estimated Granger and contemporaneous networks in Figure 4. In the Granger network plot the diameter of each vertex is proportional to the out–degree (the number of non–zero spillovers effects toward others) while in the contemporaneous network the diameter is proportional to the degree. In both plots we use the vertex color to denote the different industry groups. We exclude from the graphs the vertices that do not have any connections, which is one ticker in the Granger network and seven tickers in the contemporaneous network.

Table 4 reports the number of linkages of the Granger and contemporaneous networks of the entire panel and individual sectors. The estimated Granger volatility network has a total of 251 edges (approximately 3% of the total edges), while the contemporaneous volatility network contains 294 edges (approximately 7% of the total edges). The estimated networks share some common features. For instance, the number of industry linkages of the two networks are highly correlated and the financial sector is in particular the sector that accounts for most linkages.

We compute an in–sample $R^2$ type goodness–of–fit criteria for each series in the panel to summarise the amount of variability explained by the sparse VAR, which is defined as the proportion of variance explained by the regression equation (11). Table 4 reports the average of the $R^2$ index over the entire panel as well as the individual sectors. The index has a strong positive correlation with the number of linkages in each sector and is on average around 22%. For comparison purposes, Table 4 also reports in–sample factor and sectoral $R^2$. The factor $R^2$ is defined as the $R^2$ obtained by regressing the volatility measure on the market factor and the sector $R^2$ is defined as the $R^2$ obtained by regressing the volatility measure on the market wide and sector factor minus the factor $R^2$. The market and sector factors account for most of the variability in the series, which is roughly 56%. A back of the envelop computation shows that the networks explains around an additional 11% of the overall variability, which roughly matches the amount of variability explained by sectoral factors.

TABLE 5 AND FIGURE 5 ABOUT HERE
In order to get better insights on the industry linkages in Table 5 we report the total number of links between industry groups. It is interesting to note that after conditioning on the sectoral factors there are still a moderate number of interconnections between firms within the same industry. The table also shows that firms in the financial sector in particular have a high degree of interconnectedness across industries. In Figure 5 we report the degree distribution of the estimated networks and the distribution of the non–zero $\alpha$ and $\rho$ coefficients. As far as the degree distribution is concerned, the number of connections has a high degree of heterogeneity in the cross section. In particular, in the contemporaneous network the most interconnected tickers account for a large number of connections relative to the total. The histogram of the non–zero coefficients shows that the majority of the coefficients are positive and that positive coefficients are on average larger than the negative ones.

Last, we rank the firms in the panel on the basis of their influence in the Granger and contemporaneous networks. We measure the influence of series $j$ in the Granger and contemporaneous networks using, respectively, the indices $\sum_{i \neq j}^{N} |\hat{\alpha}_{ij}|$ and $\sum_{i \neq j}^{N} |\hat{\rho}_{ij}|$. We report the top ten most influential tickers of the Granger and contemporaneous networks according to this criteria in Table 6. The table shows clearly that large financials firms are highly influential. In particular, the results shows that the financial firms that have been heavily involved in the great financial crisis like Bank of America (BAC), AIG and Citigroup (C) are the stocks associated with the largest spillover effects in the Granger network.

Overall, the in–sample estimation results show that, after conditioning on market wide and sectoral factors, the sparse VAR captures an important proportion of overall variability, and that the financial industry in particular has the highest degree of interconnectedness.

### 5.3 Out–of–Sample Forecasting

We carry out a forecasting exercise to evaluate the out–of–sample performance of the methodology. The exercise is designed as follows. We split the sample in an in–sample period
spanning January 2nd 2004 to December 31st 2013 and an out–of–sample period spanning January 2nd 2014 to December 31st 2015. We first estimate the sparse VAR in–sample using the same steps outlined in the previous section and we then evaluate the model in the out–of–sample period.

The prediction evaluation is divided into two parts. The first part focuses on the evaluation of the nets estimator of the autoregressive component by predicting one–step–ahead volatility residuals. The benchmark forecast for this exercise is the constant zero forecast. Notice that the constant zero forecast represents the optimal forecast in case the dependence in the panel is fully captured by the factor part of model (16) without exploiting the information in the residuals. The competing forecasts are the ones obtained from a VAR model estimated via nets, univariate AR(1) models estimated by least squares, and a VAR model estimated by ridge regression (with tuning parameter chosen by Generalized Cross Validation). Note that the volatility residuals are obtained from the estimation results of model (16) estimated over the entire sample.

We report the forecasting results in the top panel of Table 7. The first row of the table reports the MSE of the benchmark while the remaining rows report the out–of–sample $R^2$ of the competitors. The out–of–sample $R^2$ index is defined as one minus the ratio of the MSE of the competing models over the MSE of the benchmark. The performance indices are averaged over the entire panel and the industry sectors. The results show that the VAR forecasts obtained by the nets estimator systematically improve forecasting ability over the benchmark by roughly 8% on average and it is the best performing forecast method overall.

The second part focuses on the evaluation of the nets estimator of the contemporaneous component by predicting the contemporaneous volatility residuals conditional on the estimated autoregressive component. We construct the series of VAR residuals $\hat{\epsilon}_{it}$ of the autoregressive component estimated by nets, and the focus is on predicting each residuals.
series conditional on the remaining ones on the basis of the regression

\[ \hat{\epsilon}_{it} = \sum_{\substack{h=1 \\ h \neq i}}^{n} \gamma_{ij} \hat{\epsilon}_{ht} + u_{it}, \quad i = 1, \ldots, n. \]

The benchmark forecast for this exercise is again the constant zero forecast, which is the optimal forecast in case the residuals do not have any cross-correlation. The competing forecasts are ones the ones obtained from the contemporaneous component of the VAR estimated by nets, the ones obtained from a linear regression estimated by least squares and a linear regression estimated by ridge regression (with tuning parameter chosen by Generalized Cross Validation). The linear regression and the ridge regression are estimated in the in-sample period using the in-sample one-step ahead forecast errors.

We report the forecasting results in the bottom panel of Table 7. The first row of the table reports the average MSE of the benchmark model while the remaining rows report the out-of-sample $R^2$ of the competitors. Results show that the nets forecasts systematically improve out-of-sample predictive ability across sectors and on average improve forecasting over the benchmark by 13%.

6 Conclusions

In this work we introduce network techniques for the analysis of lagre panels of time series. We model a panel as a VAR where the autoregressive matrices and the inverse covariance matrix of the system innovations are assumed to be sparse. The system has a natural network representation in terms of a directed graph representing predictive Granger relations and an undirected graph representing contemporaneous partial correlations. A lasso estimation algorithm called nets is introduced to estimate simultaneously the autoregressive matrices and the inverse covariance matrix of the model. The large sample properties of the estimator are established in a high-dimensional setting. The methodology is used to analyse a panel
of volatility measures of US bluechips between January 2004 and December 2015 conditional on market wide and sector specific volatility factors. The analysis shows that the series exhibit a high degree of interconnectedness and that financial firms have the highest degree of interdependence. A forecasting exercise shows that the methodology introduced in this work allows to improve forecasting over a number of benchmarks.

</table>

The table reports summary estimation results over the industry sectors and the entire panel. The first row of the table reports the outer degree of the Granger network, the second row reports the degree of the contemporaneous network, the third row reports the (in–sample) average $R^2_{t,s}$ of the nets regression. For comparison, the table reports in the fourth and fifth rows the average (in–sample) factor $R^2_{ft,s}$ and (in–sample) sector $R^2_{st,s}$, respectively.

</tbody>
</table>

The table reports the fraction of Granger and contemporaneous linkages between the industrial sectors. The (i,j) entry of the Granger linkages table is defined as the total number of linkages for sector j to sector i standardized by the total number of linkages from sector j. The (i,j) entry of the contemporaneous linkages table is defined as the total number of linkages between sector i and j standardized by the total number of linkages of sector j.

The table reports the top ten of the most interconnected series in the Granger and contemporaneous networks.
The table reports summary forecasting results over the industry sectors and the entire panel. The first panel reports forecasting exercise for the Granger component. The first row reports the MSE (times 100) of the benchmark. The second, third and fourth rows report the out–of–sample \( R^2 \) of, respectively, \( \text{nets} \), an AR(1) estimated by least squares and a VAR estimated using ridge regression. The second panel reports the forecasting exercise of the contemporaneous component. The first row reports the MSE (times 100) of the benchmark. The second, third and fourth row report the out–of–sample \( R^2 \) of, respectively, \( \text{nets} \), the linear regression estimator and the ridge estimator.
The figure displays realizations of the Erdős–Renyi random graph models used in the simulation exercise. The left picture displays a directed Erdős–Renyi graph used to generate the autoregressive matrix $A$ while the right picture displays an undirected Erdős–Renyi random graph used to generate the contemporaneous concentration matrix $C$.

The left picture displays the MSE (multiplied by 100) of the nets estimator as a function of the tuning parameter $\lambda_T$ for (from top to bottom) $T = 500, 750, 1000$. The right picture displays ROC curve of the nets estimator for (from bottom to top) $T = 250, 500, 750, 1000$. 
Figure 3: Autocorrelation and Correlation Heatmaps

The figure displays the heatmap of the sample autocorrelation (left) and sample correlation matrices of the residuals of regression (16).

Figure 4: S&P 100 Volatility Granger and Contemporaneous Networks

The figure displays the estimated Granger and contemporaneous networks. The size of the vertices is proportional to their degree and the colour of the vertices depends on their industry sector.
Figure 5: **Degree and Coefficient Distributions**

The top left and bottom left pictures display the histograms of the degree distribution of the Granger and contemporaneous networks, respectively. The top right and bottom right pictures display the histograms of the estimated non-zero $\alpha$ and $\rho$ coefficients, respectively.
A Technical appendix

A.1 Preliminary Definitions

Estimation is conditional on a given value of \( c = (c_{11} \ldots c_{nn})' \). We define the dimension of the parameters’ space as \( m = n^2p + n(n - 1)/2 \). We collect the parameters of interest in \((11)\) into the \( m \times 1 \) vector \( \theta = (\alpha', \rho')' \), where \( \alpha = (\alpha_{11}' \ldots \alpha_{1p}' \ldots \alpha_{n1}' \ldots \alpha_{np}')' \) and \( \alpha_{ik}' = (\alpha_{i1k} \ldots \alpha_{ink})' \) is the \( i \)-th row of the VAR matrix \( A_k \) with \( k = 1, \ldots, p \). The \( n(n - 1)/2 \times 1 \) vector \( \rho \) contains the stacked partial correlations of the VAR innovations. Similarly the parameters in \((10)\) are collected into the \( m \times 1 \) vector \( \phi = (\beta', \rho')' \), where \( \beta = (\beta_{11}' \ldots \beta_{1p}' \ldots \beta_{n1}' \ldots \beta_{np}')' \) and \( \beta_{ik}' = (\beta_{i1k} \ldots \beta_{ink})' \) for \( i = 1, \ldots, n \) and \( k = 1, \ldots, p \). Define as \( \theta_0, \phi_0, \) and \( c_0 \) the true values of the parameters.

With reference to the minimisation problem in \((14)-(15)\), recall that the adaptive lasso weights are defined as \( w_i = \{C \cdot |\hat{\theta}_T|^i\} \), with \( \lambda_T^G = C_{\alpha} \lambda_T \) and \( \lambda_T^C = C_{\rho} \lambda_T \). Hereafter, for simplicity and without loss of generality we assume that \( C_{\alpha} = C_{\rho} = 1 \). Moreover, we define the sample score and Hessian of the unconstrained problem as

\[
S_T(\theta, c) = \frac{1}{T} \sum_{t=1}^{T} \nabla_\theta \ell(\theta, y_t, c), \quad H_T(\theta, c) = \frac{1}{T} \sum_{t=1}^{T} \nabla_{\theta\theta} \ell(\theta, y_t, c).
\]

where \( \nabla_\theta = \partial / \partial \theta \) and \( \nabla_{\theta\theta} = \partial / \partial_{\theta\theta} \), and \( \ell(\theta, y_t, c) \) is the unconstrained loss function defined in \((12)\). The population counterparts of the above are defined as

\[
S_0(\theta, c) = E[\nabla_\theta \ell(\theta, y_t, c)], \quad H_0(\theta, c) = E[\nabla_{\theta\theta} \ell(\theta, y_t, c)].
\]

For a given symmetric matrix \( A \) we denote by \( \mu_{\text{min}}(A) \) and \( \mu_{\text{max}}(A) \) its smallest and largest eigenvalues respectively. For a generic matrix \( B \), the notation \( \|B\| = \sqrt{\mu_{\text{max}}(BB')} \) is used for spectral norm. For a generic vector \( b \), the notation \( \|b\| = \sqrt{\sum_i b_i^2} \) indicates the Euclidean norm and \( \|b\|_\infty = \max_i |b_i| \).

In what follows we use the symbol \( K \) to denote a generic positive constant. The value of \( K \) needs not to be the same from line to line. When more than one distinct constant are present in the same equation we denote them by \( K_0, K_1, K_2, \ldots \). The symbols \( \kappa_0, \kappa_1, \kappa_2, \ldots \) denote universal constants that are unique throughout the paper.
A.2 Assumptions

ASSUMPTION 1. The n-dimensional random vector process \( y_t \) is purely non-deterministic, has zero-mean, and follows the \( \text{var}(p) y_t = \sum_{k=1}^{p} A_k y_{t-k} + \epsilon_t \), where \( \epsilon_t \sim \text{i.i.d.}(0, C^{-1}) \). Moreover,

(a) \( \det(I - \sum_{k=1}^{p} A_k z^k) \neq 0 \) for any \( |z| \leq 1 \);

(b) there exists a constant \( c > 0 \) such that \( E[|y_{it}|^k] \leq k! c^{k-2} \), for any \( i = 1, \ldots, n, t = 1, \ldots, T, k = 3, 4, \ldots \);

(c) there exist couples of constants \( M_0, M_0 \) and \( M_1, M_1 \) such that

\[
0 < M_0 \leq \mu_{\min}(\Sigma(\omega)) \leq \mu_{\max}(\Sigma(\omega)) \leq M_0 < \infty, \quad 0 < M_1 \leq \mu_{\min}(C_0) \leq \mu_{\max}(C_0) \leq M_1 < \infty.
\]

where \( \Sigma(\omega) \) is the spectral density matrix of \( y_t \), defined for \( \omega \in [-\pi, \pi] \).

ASSUMPTION 2. Define the pre-estimators \( \hat{c}_T, \tilde{\theta}_T = (\tilde{\alpha}_T, \tilde{\rho}_T) \). Then, for \( T \) sufficiently large there exist constants \( C_1, C_2 > 0 \) such that, for any \( \eta > 0 \), with probability at least \( 1 - O(T^{-\eta}) \), we have

\[
\max_{1 \leq i \leq n} |\hat{c}_{T ii} - c_{0 ii}| \leq C_1 \sqrt{\log \frac{T}{T}}, \quad \max_{1 \leq i \leq m} |\tilde{\theta}_{T i} - \theta_0 i| \leq C_2 \sqrt{\log \frac{T}{T}}.
\]

A.3 Lemmas and Conditions

LEMMA 1. The parameters \( \theta \) and \( \phi \) are related by means of the equations

\[
\beta_{ijk} = \alpha_{ijk} - \sum_{l=1, l \neq i}^{n} \rho^{il} \sqrt{c_{li}} \alpha_{ljk}, \quad \gamma_{ij} = \rho^{ij} \sqrt{c_{ii}} \gamma_{ji}, \quad i, j = 1, \ldots, n, \quad k = 1, \ldots, p.
\]

Moreover, the error terms in (9) and (10) coincide, that is, \( e_{it} = u_{it} \).

LEMMA 2. For a given value of \( c \), define the \( n^2 \times n^2 \) matrix \( M(\rho; c) = (\text{diag } C)^{-1} C \otimes I_n \). Then,

\[
\begin{pmatrix}
\beta \\
\rho \\
\phi
\end{pmatrix} = \begin{pmatrix}
M(\rho; c) & \ldots & 0 & 0 \\
\vdots & \ddots & \vdots & \vdots \\
0 & \ldots & M(\rho; c) & 0 \\
0 & \ldots & 0 & I_{n(n-1)/2}
\end{pmatrix} \begin{pmatrix}
\alpha \\
\rho \\
\theta
\end{pmatrix}.
\]

LEMMA 3. Consider the mapping \( g_c : \mathbb{R}^m \to \mathbb{R}^m \), such that \( g_c(\theta) = \phi \). Then, under Assumption 4 there exists a function \( h_{c_0} : \mathbb{R}^m \to \mathbb{R}^m \) such that: \( h_{c_0}(g_{c_0}(\theta_0)) = \theta_0 \), that is \( g_{c_0} \) is invertible in \( \theta \).
CONDITION 1. Under Assumption [4] there exist constants \( L, \bar{L} \) such that

\[
0 < L \leq \mu_{\min}(H_0(\theta_0, c_0)) \leq \mu_{\max}(H_0(\theta_0, c_0)) \leq \bar{L} < \infty.
\]

CONDITION 2. Under Assumption [3] for \( T \) sufficiently large there exist constants \( C_3, C_4 > 0 \) such that, for any \( \eta > 0 \), with probability at least \( 1 - O(T^{-\eta}) \), we have

\[
\max_{1 \leq i \leq m} |S_{T,i}(\theta_0, c_0) - S_{T,i}(\theta_0, \hat{c}_T)| \leq C_3 \sqrt{\log T \over T},
\]

\[
\max_{1 \leq i, j \leq m} |H_{T,ij}(\theta_0, c_0) - H_{T,ij}(\theta_0, \hat{c}_T)| \leq C_4 \sqrt{\log T \over T}.
\]

LEMMA 4. Under Assumptions [1] and [3] and the same conditions as in Proposition [2] for \( T \) sufficiently large there exist constants \( \kappa_0, \kappa_1, \kappa_2, \kappa_3 > 0 \) such that, for any \( \eta > 0 \) and any \( u \) in \( \mathbb{R}^q_T \), with probability at least \( 1 - O(T^{-\eta}) \), we have

(a) \( \|S_{T,A}(\theta_0, \hat{c}_T)\| \leq \kappa_0 \sqrt{q_T} \sqrt{\log T \over T} \)

(b) \( \|u^T S_{T,A}(\theta_0, \hat{c}_T)\| \leq \kappa_1 \|u\| \sqrt{q_T} \sqrt{\log T \over T} \)

(c) \( \|H_{T,AA}(\theta_0, c_0) - H_{T,AA}(\theta_0, \hat{c}_T)\| \leq \kappa_2 \|u\| q_T \sqrt{\log T \over T} \)

(d) \( \|u^T H_{T,AA}(\theta_0, \hat{c}_T) - u^T H_{T,AA}(\theta_0, c_0)\| \leq \kappa_3 \|u\|^2 q_T \sqrt{\log T \over T} \)

LEMMA 5. For any subset \( S \subseteq A \cup A^c \), we have \( \hat{\theta}^S_T = \arg\min_{\theta \in \mathbb{S}_T^S} L_T(\theta, \hat{c}_T) \), where \( L_T(\theta, \hat{c}_T) \) is defined in [15], if and only if the \( i \)-th component of the sample score satisfies

\[
S_{T,i}(\hat{\theta}^S_T, \hat{c}_T) = -{\lambda_T \over |\hat{\theta}^S_T|} \text{sign}(\hat{\theta}^S_T), \quad \text{if } |\hat{\theta}^S_T| \neq 0,
\]

\[
|S_{T,i}(\hat{\theta}^S_T, \hat{c}_T)| \leq {\lambda_T \over |\hat{\theta}^S_T|}, \quad \text{if } |\hat{\theta}^S_T| = 0.
\]

If the solution is not unique then \( |S_{T,i}(\hat{\theta}^S_T, \hat{c}_T)| \leq \lambda_T |\hat{\theta}_i|^{-1} \) for some specific solution \( \hat{\theta}^S_T \), then since \( S_{T,i}(\theta, \hat{c}_T) \) is continuous in \( \theta \), then \( \hat{\theta}_i = 0 \) for all solutions \( \hat{\theta} \). Hence, if \( S = A \cup A^c \), we have the unconstrained optimisation and \( \hat{\theta}^S_T = \hat{\theta}_T \), while if \( S = A \), we have the restricted optimisation and \( \hat{\theta}^S_T = \hat{\theta}^\prime_T \).

\( \kappa_4 > 0 \) such that, for \( T \) sufficiently large and any \( \eta > 0 \),

\[
\Pr\left( 3\theta^* = \arg\min_{\hat{\theta} \in \mathcal{A}} \mathcal{L}_T(\theta, \hat{\theta}) : \theta^* \in D(\theta_0) \right) \geq 1 - O(T^{-\eta}),
\]

where \( D(\theta_0) = \{ \theta : \|\theta - \theta_0\| \leq \kappa_4 \sqrt{T} \lambda_T \} \).

**Lemma 7.** Under Assumptions 1 and 2 and under the same conditions as in Proposition 2, there exists a constant \( \kappa_5 > 0 \) such that, for \( T \) sufficiently large and any \( \eta > 0 \)

\[
\Pr\left( \| S_T(\theta, \hat{\theta}) \| > \sqrt{T} \frac{\lambda_T}{\min_{i \in A} |\theta_0|} \right) \geq 1 - O(T^{-\eta}),
\]

for any \( \theta \in S(\theta_0) \) where \( S(\theta_0) = \{ \theta : \|\theta - \theta_0\| \geq \kappa_5 \sqrt{T} \lambda_T, \theta_A^c = 0 \} \).

**Lemma 8.** Under Assumptions 1 and 2 and under the same conditions as in Proposition 3 and if \( n = O(T^\zeta) \) for some \( \zeta > 0 \), then for \( T \) sufficiently large and any \( \eta > 0 \)

\[
\Pr\left( \max_{j \in A^c} |S_{Tj}(\hat{\theta}_A^c, \hat{\theta})| \leq \frac{\lambda_T}{\max_{j \in A^c} |\hat{\theta}_j|} \right) \geq 1 - O(T^{-\eta}).
\]

### A.4 Proofs of Propositions

**Proof of Proposition 1.** Notice that the loss related to (10) is given by

\[
\ell(\phi_0; y_t, c_0) = \sum_{i=1}^{n} \left( y_{it} - \sum_{k=1}^{p} \sum_{j=1}^{n} \beta_{ijk} y_{jt-k} - \sum_{h=1}^{n} \rho_{ih} \sqrt{\frac{c_{0,hh}}{c_{0,ii}}} y_{ht} \right)^2.
\]

Clearly \( \phi_0 \) is a minimizer of (A-1) (using Assumption 3 for second order conditions):

\[
\phi_0 = \arg\min_{\phi} \mathbb{E}[\ell(\phi; y_t, c_0)].
\]

In order for \( \theta_0 \) to be a minimum, we need to verify that first and second order conditions hold. The first order conditions are given by

\[
\mathbb{E}[\nabla_\phi \ell(\theta_0; y_t, c_0)] = \mathbb{E}[\nabla_\phi \ell(\phi_0; y_t, c_0) \nabla_\phi g_{c_0}(\theta_0)] = \mathbb{E}[\nabla_\phi \ell(\phi_0; y_t, c_0)] \nabla_\phi g_{c_0}(\theta_0) = 0,
\]

\( ^6 \)Notice that we can exchange integral and differentiation operators as the loss function is such that \( \ell \in C^\infty(\mathbb{R}^m) \).
since \( E[\nabla \ell(\phi_0; y_t, c_0)] = 0 \) because of (A-2). The second order conditions are
\[
E[\nabla \theta \ell(\theta_0; y_t, c_0)] = E[\nabla \theta \ell(\phi_0; y_t, c_0)] + E[\nabla \phi \ell(\phi_0; y_t, c_0)] \nabla \theta g_{c_0}(\theta_0)
\]

which we used (A-3). Now, (A-4) is positive definite since the first term is positive definite because of (A-2) and the second term is positive definite because of Lemma 3. □

**Proof of Proposition 2.** From Lemma 5, we have
\[
\|S_T A(\hat{\theta}_T^A)\| \leq \lambda_T \max_{i \in A} \frac{1}{|\theta_{T,i}|}.
\]

Moreover, for any \( i \in A \),
\[
\frac{1}{|\theta_{T,i}|} = \frac{1}{|\theta_{T,i}|} \leq \frac{1}{|\theta_{0,i}|} + \sqrt{\frac{2}{|\theta_{0,i}|} |\theta_{T,i} - \theta_{0,i}| + o(|\theta_{T,i} - \theta_{0,i}|}). \tag{A-5}
\]

Define \( \theta_0^* = \min_{i \in A} |\theta_{0,i}| \) and notice that \( \theta_0^* > 0 \) and define also \( \nu_T = \sqrt{T} \lambda_T \), therefore \( \nu_T \to 0 \) as \( T \to \infty \). Using Assumption 2 and (A-5), there exists a constant \( K > 0 \) such that for \( T \) sufficiently large and for any \( \eta > 0 \), we have with probability at least \( 1 - O(T^{-\eta}) \)
\[
\|S_T A(\hat{\theta}_T^A)\| \leq \sqrt{T} \|S_T A(\hat{\theta}_T^A)\|_\infty \leq \nu_T \max_{i \in A} \frac{1}{|\theta_{T,i}|} \leq \nu_T \left[ \max_{i \in A} \frac{1}{|\theta_{0,i}|} + K \left( \frac{\log T}{T} \right)^{1/4} \right] \leq \frac{\nu_T}{\theta_0^*} + \nu_T K \left( \frac{\log T}{T} \right)^{1/4}. \tag{A-6}
\]

Notice that the last term on the rhs of (A-6) is \( o(\nu_T) \), thus it can be neglected so that for \( T \) sufficiently large and for any \( \eta > 0 \), we have
\[
\Pr \left( \|S_T A(\hat{\theta}_T^A)\| \leq \frac{\nu_T}{\theta_0^*} \right) \geq 1 - O(T^{-\eta}). \tag{A-7}
\]

From Lemma 7, we also have that for \( T \) sufficiently large and for any \( \eta > 0 \)
\[
\Pr \left( \|S_T A(\theta)\| \leq \frac{\nu_T}{\theta_0^*} \right) \geq 1 - O(T^{-\eta}). \tag{A-8}
\]

for any \( \theta \) such that \( \theta_{Ac} = 0 \) and \( \|\theta - \theta_0\| < \kappa_5 \nu_T \). Therefore, (A-8) implies that inside a disc of radius \( \kappa_5 \nu_T \) condition (A-7) is satisfied. In particular, (A-7) is a consequence of the Karush-Kuhn-Tucker condition in
Lemma 5 for $\hat{\theta}_T^A$ to be a minimum. Moreover, by Lemma 6 such minimum always exists in a disc of radius $\kappa_4 \nu_T$. Hence, if we define $\kappa_R = \min(\kappa_4, \kappa_5)$, for $T$ sufficiently large and for any $\eta > 0$, we have

$$\Pr \left( \| \hat{\theta}_T^A - \theta_{0,A} \| \leq \kappa_R \nu_T \right) \geq 1 - O(T^{-\eta}). \quad (A-9)$$

Finally, for any $i \in A$ and for $T$ sufficiently large, we have $|\theta_{0i}| > s_T > 2\kappa_R\nu_T$. Moreover, for any $i \in A$, in general we have

$$\Pr \left( \text{sign}(\hat{\theta}_T^A) = \text{sign}(\theta_{0i}) \right) \geq \Pr \left( \| \hat{\theta}_T^A - \theta_{0,A} \| \leq \kappa_R \nu_T, |\theta_{0i}| > 2\kappa_R \nu_T \right), \quad (A-10)$$

which by (A-9) implies sign consistency. This completes the proof. \square

PROOF OF PROPOSITION 3. (a) By Proposition 2 and Lemma 7 the non-zero coefficients of $\hat{\theta}_T^A$ satisfy the Karush-Kuhn-Tucker condition in Lemma 5. Moreover, by Lemma 8 for $T$ sufficiently large and for any $\eta > 0$ also the zero coefficients satisfy the Karush-Kuhn-Tucker condition with probability at least $1 - O(T^{-\eta})$. Therefore, since with probability at least $1 - O(T^{-\eta})$ the restricted estimator $\hat{\theta}_T^A$ is also a solution of the unrestricted problem, we proved the existence of a solution of the unrestricted problem. On the other hand, by Lemma 8 and the Karush-Kuhn-Tucker condition in Lemma 5, with probability at least $1 - O(T^{-\eta})$, any solution of the unrestricted problem is a solution of the restricted problem. That is,

$$\Pr \left( \hat{\theta}_T^A = \hat{\theta}_{T,A} \right) \geq 1 - O(T^{-\eta}). \quad (A-11)$$

As a consequence of (A-11), given the unrestricted estimator, $\hat{\theta}_{T,A}$, for $T$ sufficiently large, for any $\eta > 0$ and for all $j \in A^c$ we have

$$\Pr \left( \hat{\theta}_{T,j} = 0 \right) = \Pr \left( \hat{\theta}_{T,j} = 0 \mid \hat{\theta}_T^A = \hat{\theta}_{T,A} \right) \Pr \left( \hat{\theta}_T^A = \hat{\theta}_{T,A} \right) + \Pr \left( \hat{\theta}_{T,j} = 0 \mid \hat{\theta}_T^A \neq \hat{\theta}_{T,A} \right) \Pr \left( \hat{\theta}_T^A \neq \hat{\theta}_{T,A} \right) \geq \Pr \left( \hat{\theta}_{T,j} = 0 \mid \hat{\theta}_T^A = \hat{\theta}_{T,A} \right) \Pr \left( \hat{\theta}_T^A = \hat{\theta}_{T,A} \right) = \Pr \left( \hat{\theta}_T^A = \hat{\theta}_{T,A} \right) \geq 1 - O(T^{-\eta}).$$

This proves part (a). Part (b) follows directly from Proposition 2 and (A-11). This completes the proof. \square
B Proofs of Complementary Results

Proof of lemma 1. The VAR\((p)\) model \((1)\) has \(n\) equations given by

\[
y_{it} = \sum_{k=1}^{p} \sum_{j=1}^{n} \alpha_{ijk} y_{jt-k} + \epsilon_{it}, \quad i = 1, \ldots, n, \tag{A-12}\]

where \(\epsilon_{it}\) is the \(i\)-the element of the vector \(\epsilon_t\). Then, by substituting \(\text{(A-12)}\) in \(\text{(10)}\), we have, for any \(i = 1, \ldots, n\),

\[
y_{it} = \sum_{k=1}^{p} \sum_{j=1}^{n} \beta_{ijk} y_{jt-k} + \sum_{h=1}^{n} \gamma_{ih} \epsilon_{ht} + \epsilon_{it}
\]

\[
= \sum_{k=1}^{p} \sum_{j=1}^{n} \left( \beta_{ijk} \sum_{h=1}^{n} \gamma_{ih} \alpha_{hjk} y_{jt-k} + \gamma_{ih} \epsilon_{ht} \right) + \epsilon_{it}
\]

\[
= \sum_{k=1}^{p} \sum_{j=1}^{n} \left( \beta_{ijk} \sum_{h=1}^{n} \gamma_{ih} \alpha_{hjk} y_{jt-k} + \gamma_{ih} \epsilon_{ht} + \epsilon_{it} \right).
\tag{A-13}
\]

By comparing the rhs of \(\text{(A-13)}\) with \(\text{(A-12)}\) we have

\[
\alpha_{ijk} = \beta_{ijk} + \sum_{h=1}^{n} \gamma_{ih} \alpha_{hjk}, \quad i, j = 1, \ldots, n, \quad k = 1, \ldots, p, \tag{A-14}\]

\[
\epsilon_{it} = \sum_{h=1}^{n} \gamma_{ih} \epsilon_{ht} + \epsilon_{it}, \quad i = 1, \ldots, n. \tag{A-15}
\]

and therefore, from \(\text{(9)}\) we also have \(\epsilon_{it} = u_{it}\). From \(\text{(A-15)}\) using Lemma 3 in Peng et al. (2009) we have

\[
\gamma_{ih} = \rho^{ih} \sqrt{\frac{\epsilon_{kk}}{\epsilon_{tt}}}, \quad i, h = 1, \ldots, n, \tag{A-16}\]

and clearly when \(i = h, \gamma_{ih} = \rho^{ih} = 1\). By substituting \(\text{(A-16)}\) into \(\text{(A-14)}\) we complete the proof. \(\Box\)

Proof of lemma 2. First define the \(n \times n\) matrix \(R = I_n - \text{diag} \ C^{-1/2} \text{diag} \ C^{-1/2}\). Form the definition of partial correlation \((4)\), we see that \(R\) is a matrix with \(\rho^{ij}\) as generic \((i, j)\) entry whenever \(i \neq j\) and zero otherwise. Now from Lemma 1 we immediately have that, for any \(k = 1, \ldots, p\)

\[
\begin{pmatrix}
\beta_{1k} \\
\vdots \\
\beta_{nk}
\end{pmatrix} = \left\{ I_n^2 - \left[ \text{diag} \ C^{-1/2} R \text{diag} \ C^{1/2} \right] \otimes I_n \right\} \begin{pmatrix}
\alpha_{1k} \\
\vdots \\
\alpha_{nk}
\end{pmatrix}
\]

\[
= \left\{ I_n^2 - \left[ (I_n - \text{diag} \ C^{-1}) \otimes I_n \right] \right\} \begin{pmatrix}
\alpha_{1k} \\
\vdots \\
\alpha_{nk}
\end{pmatrix} = M(\rho; c) \begin{pmatrix}
\alpha_{1k} \\
\vdots \\
\alpha_{nk}
\end{pmatrix}. \tag{A-17}
\]

The statement of the lemma follow straightforwardly from \(\text{(A-17)}\). \(\Box\)
Proof of Lemma 3. From Lemma 2 we have

\[ g_{c_0}(\theta_0) = \phi_0 = \left( \begin{array}{ccc} M(\rho_0; c_0) & \ldots & 0 \\ 0 & \ldots & 0 \\ 0 & \ldots & 0 \end{array} \right) \theta_0. \]

Then consider the Jacobian \( \nabla_{\theta} g_{c_0}(\theta_0) \) which has \((i, j)\)-th entry \( \partial g_{c_0,i}(\theta_0)/\partial \theta_j = \partial \phi_i/\partial \theta_j \):

\[ \nabla_{\theta} g_{c_0}(\theta_0) = \left( \begin{array}{ccc} M(\rho_0; c_0) & \ldots & 0 \\ 0 & \ldots & 0 \end{array} \right) \nabla_{\rho} M(\rho_0; c_0)(\alpha_{0,11} \ldots \alpha_{0,n1})^t. \]  

(A-18)

Since \( M(\rho_0; c_0) \) is positive definite because of Assumption 1, the Jacobian in \( \theta_0 \) is positive definite too and the mapping \( g_{c_0} \) is invertible in \( \theta_0 \) and this completes the proof.

Proof of Condition 1. The inequality on the lhs is proved in the proof of Proposition 1, while the inequality on the rhs is proved in condition B1 in the supplementary appendix of Peng et al. (2009).

Proof of Condition 2. This is an immediate consequence of consistency of the pre-estimator \( \hat{\theta}_T \) given in Assumption 2 and the continuous mapping theorem.

Proof of Lemma 4. (a) We begin by noting that the sample averages of the partial derivatives of \( \ell \) in \((\theta'_0, c'_0)^t\) satisfy a Bernstein–type exponential inequality. The partial derivatives of \( \ell \) are

\[ \frac{\partial \ell(\theta_0, y_t, c_0)}{\partial c_{0,i}} = -2u_t y_i + \sum_{l=1}^n 2\rho_l^i \sqrt{\frac{c_{0,ii}}{c_{0,ll}}} u_{lt} y_j t - k, \]

\[ \frac{\partial \ell(\theta_0, y_t, c_0)}{\partial \rho_l^i} = -2 \sqrt{\frac{c_{0,ii}}{c_{0,jj}}} u_{lt} y_j t - k - 2 \sqrt{\frac{c_{0,ij}}{c_{0,ii}}} u_j t e_l t. \]

We only show this for the partial derivatives with respect to the \( \alpha \) coefficients. The proof for the partial derivatives of the \( \rho \) coefficients follows analogous steps. In particular, we that show that the averages of the partial derivatives of the the \( \alpha \) coefficients satisfy an exponential inequality that does not depend on \( n \). From [9] we have \( \text{Var}(u_{lt}) \leq \text{Var}(e_{lt}) \) for any \( l = 1, \ldots, n \), therefore, there exists a constant \( K > 0 \) such that

\[ \text{Var} \left( \sum_{l=1}^n \rho_l^i \sqrt{\frac{c_{0,ii}}{c_{0,ll}}} u_{lt} t \right) \leq \text{Var} \left( \sum_{l=1}^n \rho_l^i \sqrt{\frac{c_{0,ii}}{c_{0,jj}}} e_{lt} t \right) = \text{Var}(e_{lt}) \leq K, \]

(A-19)

where the last equality is given in [9]. Define

\[ A_T t = -2 \frac{T}{T} \sum_{l=1}^T u_{lt} y_j t - k, \]

\[ B_T t = 2 \frac{T}{T} \sum_{l=1}^T \sum_{l \neq i}^n \rho_l^i \sqrt{\frac{c_{0,ii}}{c_{0,ll}}} u_{lt} y_{jt} t - k. \]

By Assumption 1, \( y_{it} \) is a strongly mixing process. Thus, \( |T^{-1} \sum_{l=1}^T y_{lt}| \) satisfy the Bernstein-type exponential inequality in Theorem 1 by Doukhan and Neumann (2007) (see also Theorem 1.4 in Bosq 1996), i.e. for any \( i \) there exists a constant \( K_0 > 0 \) such that, for any \( \varepsilon > 0, \)

\[ \text{Pr} \left( \left| \frac{1}{T} \sum_{l=1}^T y_{lt} \right| > \varepsilon \right) \leq \exp \left\{ -K_0 \varepsilon^2 \right\}. \]

(A-20)
Then, for $T$ that for $\delta$ By setting the rhs of the last expression equal to $\text{Lang, León, Louhichi, and Prieur (2007), there exists also a constant $K_1 > 0$ such that}

$$\Pr(|A_{T,ijk}| > \varepsilon) \leq \exp\{-K_1 T \varepsilon^2\}.$$  \hspace{1cm} (A-21)

Moreover, by Assumption [1] for any $i = 1, \ldots, n$ we have $0 < c_0_{ii} < \infty$ and therefore because of (A-19) each term in parenthesis in $B_{T,ijk}$ has finite variance and zero mean, therefore, using arguments analogous to those used for (A-21), there exists also a constant $K_2 > 0$ such that

$$\Pr(|B_{T,ijk}| > \varepsilon) \leq \exp\{-K_2 T \varepsilon^2\}.$$  \hspace{1cm} (A-21)

Therefore, there exists a constant $K_3 > 0$ such that

$$\Pr\left(\left| \frac{1}{T} \sum_{t=1}^{T} \frac{\partial \ell(t_0, y_t, c_0)}{\partial a_{0,ijk}} \right|^2 > \varepsilon^2 \right) = \Pr(|A_{T,ijk} + B_{T,ijk}| > \varepsilon) \leq \Pr(|A_{T,ijk}| + |B_{T,ijk}| > \varepsilon) \leq 2 \exp\{-K_3 T \varepsilon^2\}.$$  

Note that as a consequence there exist a constant $K_4 > 0$ such that

$$\Pr(\|S_{T,A}(t_0, c_0)\| > \varepsilon) = \Pr(\|S_{T,A}(t_0, c_0)\|^2 > \varepsilon^2) = \Pr\left(\sum_{i=1}^{qT} |S_{T,A,i}|^2 > \varepsilon^2 \right),$$

$$\leq qT \Pr\left(|S_{T,A,i}|^2 > \frac{\varepsilon^2}{qT} \right) = qT \Pr\left(|S_{T,A,i}| > \frac{\varepsilon}{\sqrt{qT}} \right),$$

$$\leq 2qT \exp\left\{-K_4 T \frac{\varepsilon^2}{qT} \right\}.$$  \hspace{1cm} (A-22)

By setting the rhs of the last expression equal to $\delta = O(T^{-\eta})$ for $\eta > 0$ and solving with respect to $\varepsilon$ we get that for $T$ sufficiently large there exist a constant $\kappa_0$ such that

$$\varepsilon \leq \kappa_0 \sqrt{qT} \sqrt{\frac{\log T}{T}}.$$  \hspace{1cm} (A-22)

Then, for $T$ sufficiently large there exist a constant $\kappa_0$ such that

$$\|S_{T,A}(t_0, c_0)\| < \kappa_0 \sqrt{qT} \sqrt{\frac{\log T}{T}},$$

with at least probability $1 - O(T^{-\eta})$. Moreover, we have

$$\|S_{T,A}(t_0, \hat{c}_T)\| \leq \|S_{T,A}(t_0, c_0)\| + \|S_{T,A}(t_0, c_0) - S_{T,A}(t_0, \hat{c}_T)\|$$  \hspace{1cm} (A-23)

and for $T$ sufficiently large the second term is $O(\sqrt{qT \log T} T^{-\eta}) = o(1)$ by Condition 2. Part (a) follows by combining (A-22) and (A-23). Part (b) follows from (a) and the Cauchy-Schwarz inequality.

(c) We begin by noting that

$$\|H_{T,A,A}(t_0, c_0)u - H_{0,A,A}(t_0, c_0)u\|^2 \leq 2\|u\|^2 \|H_{T,A,A}(t_0, c_0) - H_{0,A,A}(t_0, c_0)\|^2,$$

$$\leq 2\|u\|^2 \sum_{i=1}^{qT} \sum_{j=1}^{qT} [H_{T,A,A,ij}(t_0, c_0) - H_{0,A,A,ij}(t_0, c_0)]^2.$$  

Next, we focus on showing that the differences

$$A_{T,ij} = H_{T,A,A,ij}(t_0, c_0) - H_{0,A,A,ij}(t_0, c_0)$$

satisfy an appropriate Bernstein–type exponential inequality. We begin by noting that the first $n^2 p \times n^2 p$
Assumption 1 and the same arguments leading to (A-21) there exists a constant \( K \) get that for \( n \) not grow with \( n \) and any \( k, k' = 1 \ldots p \) and

\[
\frac{\partial^2 \ell(\theta_0, y_\ell, c_0)}{\partial \alpha_{i,j'} \partial \alpha_{i,j}} = 2y_{j' \cdot k} y_{j' \cdot k'} \left( 1 - \rho_0^{ij} \sqrt{c_0 ii / c_0 ll} \right) + \sum_{l=1}^{n} \rho_0^{il} \sqrt{c_0 ii / c_0 ll} \left( \rho_0^{ij} \sqrt{c_0 ii / c_0 ll} - 1 \right),
\]

for \( i \neq i' \) and any \( j, j' = 1 \ldots n \) and any \( k, k' = 1 \ldots p \). The second \( n(n-1)/2 \times n(n-1)/2 \) diagonal block has entries

\[
\frac{\partial^2 \ell(\theta_0, y_\ell, c_0)}{\partial \rho_{i,j} \partial \rho_{i,j'}} = 2 \sqrt{c_0 ii / c_0 jj} \cdot c_{j' \cdot t} c_{j \cdot t},
\]

for any \( i, j, j' = 1 \ldots n \) with \( i \neq j, i \neq j' \) and \( j \neq j' \). It is straightforward to check that the averages of the partial derivatives with respect to the \( \rho \) coefficients satisfy a Bernstein–type concentration inequality. Thus, there exists a constant \( K_1 > 0 \) such that

\[
\sum_{l=1}^{n} |\rho_0^{ij}| \leq \sum_{l=1}^{n} (\rho_0^{ij})^2 \leq \frac{\text{Var}(\epsilon_i t)}{\mu_{\min}(C_0^2)} = \text{Var}(\epsilon_i t) \mu_{\max}(C_0) < K_1. \tag{A-24}
\]

Thus, given (A-24), and since by Assumption 1 we have \( 0 < c_{0 ii} < \infty \) for any \( i = 1, \ldots, n \), there exists a constant \( K_2 > 0 \) such that

\[
\left| \sum_{l=1}^{n} \rho_0^{il} \sqrt{c_0 ii / c_0 ll} \left( \rho_0^{ij} \sqrt{c_0 ii / c_0 ll} - 1 \right) \right| \leq \sum_{l=1}^{n} (\rho_0^{ij})^2 + \sum_{l=1}^{n} |\rho_0^{ij}| \sqrt{c_0 ii / c_0 ll} < K_2.
\]

By the Cauchy–Schwartz inequality, we have that the mixed partial derivatives with respect to \( \alpha \) and \( \rho \) also not grow with \( n \) and satisfy a Bernstein–type concentration inequality. Thus, there exists a constant \( K_3 > 0 \) such that \( |A_{ijk'j'-k'}| \leq K_3 |dy_j \cdot k - E[dy_j \cdot k]| \) for any \( (i, j, k) \) and \( (i', j', k') \). Therefore, by Assumption 1 and the same arguments leading to (A-21) there exists a constant \( K_4 > 0 \) such that

\[
\Pr \left( \sum_{i=1}^{q_T} \sum_{j=1}^{q_n} |A_{ij}|^2 \geq \varepsilon^2 \right) \leq q_T^2 \Pr \left( |A_{ij}| \geq \varepsilon \right) \leq 2q_T^2 \exp \left( -K_4 T \varepsilon^2 / q_T^2 \right).
\]

By setting the rhs of the last expression equal to \( \delta = O(T^{-\eta'}) \) for \( \eta' > 0 \) and solving with respect to \( \varepsilon \) we get that for \( T \) sufficiently large there exist a constant \( \kappa_2 > 0 \) such that

\[
\varepsilon \leq \kappa_2 q_T \sqrt{\frac{\log T}{T}}.
\]

Finally, for \( \eta > 0 \) and \( T \) sufficiently large there exists a constant \( \kappa_2 \) such that

\[
\|H_{T, \Lambda}(\theta_0, c_0) u - H_{0, \Lambda}(\theta_0, c_0) u\| < \kappa_2 \|u\|^2 q_T \sqrt{\frac{\log T}{T}},
\]

with at least probability \( 1 - O(T^{-\eta}) \). Part (c) follows as part (a) by using Condition 2 and the conditions in
the statements of Propositions 2 and 3. Part (d) follows from (c) and the Cauchy-Schwarz inequality. This completes the proof.

\[ \square \]

**Proof of Lemma 5** See Lemma 2.1 in Bühlmann and van de Geer (2011).

**Proof of Lemma 6** Define \( \nu_T = \sqrt{q_T} \lambda_T \), therefore \( \nu_T \to 0 \) as \( T \to \infty \). Consider a generic vector \( u \in \mathbb{R}^m \) such that \( u_{A^c} = 0 \) and \( \|u\| = C \). Define \( L_T(\theta, c) = \frac{1}{p} \sum_{i=1}^{T} \ell(\theta, y_i, c) \) and \( \ell(\theta, y_i, c) \) is the unconstrained loss function defined in (12). The increment of the sample loss defined in (14)-(15) is

\[
Q_T(\theta_0 + \nu_T u) = \frac{1}{T} \left( C_T(\theta_0 + \nu_T u, \hat{c}) - C_T(\theta_0, \hat{c}) \right) = \left[ L_T(\theta_0 + \nu_T u, \hat{c}) - L_T(\theta_0, \hat{c}) \right] - \lambda_T \sum_{i=1}^{m} \frac{|\theta_{0i}| - |\theta_{0i} + \nu_T u_i|}{|\theta_{T_i}|}
\]

\[
\geq \left[ L_T(\theta_0 + \nu_T u, \hat{c}) - L_T(\theta_0, \hat{c}) \right] - \lambda_T \nu_T \sum_{i=1}^{m} \frac{|u_i|}{|\theta_{T_i}|}.
\]

(A-25)

Start from the first term in (A-25). By Lemma 4 for \( T \) sufficiently large and for any \( \eta > 0 \), we have with probability at least \( 1 - O(T^{-\eta}) \)

\[
L_T(\theta_0 + \nu_T u, \hat{c}) - L_T(\theta_0, \hat{c}) = \nu_T u_A^T S_{T,A}(\theta_0, \hat{c}) + \frac{1}{2} \nu_T^2 u_A^T H_{T,A,A}(\theta_0, \hat{c}) u_A
\]

(A-26)

\[
= \nu_T u_A^T S_{T,A}(\theta_0, \hat{c}) + \frac{1}{2} \nu_T^2 u_A^T H_{0,A,A}(\theta_0, \hat{c}) u_A + \frac{1}{2} \nu_T^2 u_A^T \left( H_{T,A,A}(\theta_0, \hat{c}) - H_{0,A,A}(\theta_0, c_0) \right) u_A + o(\nu_T^2)
\]

\[
\geq - \kappa_1 \|u_A\| \sqrt{q_T} \sqrt{\left( \log \frac{T}{T} \right) \lambda_T \nu_T} - \kappa_2 \|u_A\|^2 q_T \sqrt{\left( \log \frac{T}{T} \right) \nu_T^2} + \frac{1}{2} \nu_T^2 u_A^T H_{0,A,A}(\theta_0, c_0) u_A.
\]

By the conditions given in the statements of Propositions 2 and 3 and since \( \|u_A\| = C \), for the first and second term on the rhs of (A-26) we have

\[
- \kappa_1 C \sqrt{q_T} \sqrt{\left( \log \frac{T}{T} \right) \lambda_T \nu_T} = \nu_T^2 o(1) = o(\nu_T^2),
\]

(A-27)

\[
- \kappa_2 C^2 q_T \sqrt{\left( \log \frac{T}{T} \right) \nu_T^2} = \nu_T^2 o(1) = o(\nu_T^2),
\]

(A-28)

and both terms can be neglected for \( T \) sufficiently large. Moreover, by Condition I we have

\[
\frac{1}{2} \nu_T^2 u_A^T H_{0,A,A}(\theta_0, c_0) u_A \geq \frac{1}{2} \nu_T^2 C^2 \mu_{\min}(H_{0,A,A}) \geq \frac{1}{2} \nu_T^2 C^2 L > 0.
\]

(A-29)

Then, notice that, by Cauchy-Schwarz inequality,

\[
\left( \sum_{i=1}^{m} \frac{|u_i|}{|\theta_{T_i}|} \right)^2 \leq C^2 \sum_{i=1}^{m} \frac{1}{\theta_{T_i}^2}.
\]

(A-30)

Moreover, for any \( i \in A \),

\[
\frac{1}{\theta_{T_i}^2} = \frac{1}{\theta_{0i}^2} - \frac{2 \theta_{0i} (\tilde{\theta}_{T_i} - \theta_{0i}) + o((\tilde{\theta}_{T_i} - \theta_{0i}))}{\theta_{0i}^4} \leq \frac{1}{\theta_{0i}^2} + \frac{2}{\theta_{0i}^3} |\tilde{\theta}_{T_i} - \theta_{0i}| + o(|\tilde{\theta}_{T_i} - \theta_{0i}|).
\]

(A-31)

Define \( \theta_{0 \text{min}} = \min_{i \in A} \theta_{0i} \) and notice that \( |\theta_{0 \text{min}}| > 0 \). Then, combining Assumption 2 and (A-31), there exists a constant \( K > 0 \) such that for \( T \) sufficiently large and for any \( \eta > 0 \), we have with probability at least

49
Proof of lemma 8.

\[ C^2 \sum_{i=1}^{m} \frac{1}{\theta_{Ti}} \leq C^2 q_T + C^2 K q_T \sqrt{\log T \over T}. \]  

(A-32)

Therefore, using (A-30) and (A-32), for the second term in (A-25), for \( T \) sufficiently large and for any \( \eta > 0 \), with probability at least \( 1 - O(T^{-\eta}) \), we have

\[-\lambda_T \nu_T \sum_{i=1}^{m} \frac{|u_i|}{\theta_{Ti}} \geq -\lambda_T \nu_T C \sqrt{q_T} \left[ \frac{1}{\theta_{0 min}} + \sqrt{K \left( \log T \over T \right)^{1/4}} \right] \]

\[ \geq -\nu_T^2 \frac{C}{\theta_{0 min}} + \nu_T \sqrt{K \left( \log T \over T \right)^{1/4}}, \]  

(A-33)

and notice that the last term is \( o(\nu_T^2) \), thus it can be neglected for \( T \) sufficiently large. Then, by substituting (A-26) and (A-33) in (A-25), and using (A-27), (A-28), and (A-29), we have, for \( T \) sufficiently large and for any \( \eta > 0 \),

\[ \Pr \left( Q_T(\theta_0 + \nu_T u) \geq 1 \right) \geq \Pr \left( \inf_{u : \|u\| = C} Q_T(\theta_0 + \nu_T u) > 0 \right) \geq 1 - O(T^{-\eta}). \]

Thus, if we choose \( C = 2/(L/\theta_{0 min}) + \epsilon \), for any \( \epsilon > 0 \), then for \( T \) sufficiently large and for any \( \eta > 0 \)

\[ \Pr \left( \inf_{u : \|u\| = C} Q_T(\theta_0 + \nu_T u) > 0 \right) \geq 1 - O(T^{-\eta}), \]

which means that there exists a local minimum for the restricted problem within the disc \( D(\theta_0) = \{ \theta : \| \theta - \theta_0 \| \leq \nu_T C \} \), with probability at least \( 1 - O(T^{-\eta}) \). By choosing \( \kappa_4 = C \), we complete the proof. \( \square \)

Proof of lemma 7. Define \( \nu_T = \sqrt{q_T} \lambda_T \), therefore \( \nu_T \to 0 \) as \( T \to \infty \). Then, any \( \theta \in S(\theta_0) \) can be written as \( \theta = \theta_0 + \nu_T u \), where \( u_{A^c} = 0 \), \( \| u \| \geq \kappa_5 \), and \( \| u \| \leq C < \infty \). For any \( \theta \in S(\theta_0) \), we can write

\[ S_{T,A}(\theta, \hat{c}_T) = S_{T,A}(\theta_0, \hat{c}_T) + \nu_T H_{T,A}(\theta_0, \hat{c}_T) u \]

\[ = S_{T,A}(\theta_0, \hat{c}_T) + \nu_T \left( H_{T,A}(\theta_0, \hat{c}_T) - H_{0,A}(\theta_0, c_0) \right) u + \nu_T H_{0,A}(\theta_0, c_0) u + o(\nu_T). \]

Thus, by Lemma 4, for \( T \) sufficiently large and for any \( \eta > 0 \), we have, with probability at least \( 1 - O(T^{-\eta}) \),

\[ \| S_{T,A}(\theta, \hat{c}_T) \| \geq -\kappa_5 \sqrt{q_T} \sqrt{\log T \over T} + \kappa_2 \| u \| \nu_T \sqrt{q_T} \sqrt{\log T \over T} + \nu_T \| H_{0,A}(\theta_0, c_0) u \|. \]

The first and second term on the rhs of the last expression are both \( o(\nu_T) \). Then, using Condition 1 for \( T \) sufficiently large and for any \( \eta > 0 \), with probability at least \( 1 - O(T^{-\eta}) \) we have

\[ \| S_{T,A}(\theta, \hat{c}_T) \| \geq \nu_T \| H_{0,A}(\theta_0, c_0) u \| \geq \nu_T L_{0} \kappa_5. \]

Define \( \theta_{0}^* = \min_{i \in A} | \theta_{0i} | \) and notice that \( \theta_{0}^* > 0 \). By choosing \( \kappa_5 = 1/(L_{\theta}^*) + \epsilon \) for any \( \epsilon > 0 \), we complete the proof. \( \square \)

Proof of lemma 8. In the following define \( \nu_T = (\hat{\theta}_T^A - \theta_0) \). For any \( j \in A^c \) we have

\[ S_{T,j}(\hat{\theta}_T^A, \hat{c}_T) = \underbrace{S_{T,j}(\theta_0, \hat{c}_T)}_{A_{T,j}} + \underbrace{H_{T,j}(\theta_0, \hat{c}_T) v_T + o(\| v_T \|)}_{A_{2T,j}} + \underbrace{\left[ H_{T,j}(\theta_0, \hat{c}_T) - H_{0,j}(\theta_0, c_0) \right] v_T + o(\| v_T \|)}_{A_{3T,j}}. \]

(A-34)
Start from the first term on the rhs of (A-34). By an argument analogous to the proof of Lemma 4 (a) we have that for $T$ sufficiently large and for any $\eta' > 0$ there exists a constant $K_1 > 0$ such that

$$\Pr \left( |A_{1Tj}| \leq K_1 \sqrt{\frac{\log T}{T}} \right) \geq 1 - O(T^{-\eta'}).$$  \hfill (A-35)

For the second term on the rhs of (A-34) from Condition 1 we have

$$|A_{2Tj}| \leq \|H_0j(\theta_0, c_0)\| \|v_T\| \leq \mu_{\text{max}}(H_0(\theta_0, c_0)) \|v_T\| \leq \tilde{T} \|v_T\|.$$  \hfill (A-36)

Therefore, if we define $K_2 = \kappa_R \tilde{T}$, by Proposition 2 we have that for $T$ sufficiently large and for any $\eta' > 0$

$$\Pr (|A_{2Tj}| \leq K_2 \sqrt{\frac{q_T}{\lambda_T}}) \geq 1 - O(T^{-\eta'}).$$  \hfill (A-37)

For the third term on the rhs of (A-34), we have

$$|A_{3Tj}| \leq \|H_Tj(\theta_0, c_T) - H_0j(\theta_0, c_0)\| \|v_T\|.$$  \hfill (A-38)

Then, using an argument similar to the proof of Lemma 4 (c) and by Proposition 2 and by defining $K_3 = \kappa_2 \kappa_R$ we have that for $T$ sufficiently large and for any $\eta' > 0$

$$\Pr \left( |A_{3Tj}| \leq K_3 \sqrt{\frac{q_T}{\lambda_T}} \right) \geq 1 - O(T^{-\eta'}).$$  \hfill (A-39)

Moreover, by Assumption 2 there exists a constant $K_4 > 0$ such that for $T$ sufficiently large and for any $\eta' > 0$ we have

$$\Pr \left( \frac{1}{\max_{j \in A^c} |\theta_{Tj}|} > K_4 \sqrt{\frac{T}{\log T}} \right) \geq 1 - O(T^{-\eta'}).$$  \hfill (A-40)

From (A-38) and (A-34) we have

$$\Pr \left( |S_Tj(\hat{\theta}^A_T, \hat{c}_T)| \leq \frac{\lambda_T}{\max_{j \in A^c} |\theta_{Tj}|} \right) \geq \Pr \left( |A_{1Tj}| + |A_{2Tj}| + |A_{3Tj}| \leq \frac{\lambda_T}{\max_{j \in A^c} |\theta_{Tj}|} \right) \geq \Pr \left( |A_{1Tj}| + |A_{2Tj}| + |A_{3Tj}| \leq K_4 \lambda_T \sqrt{\frac{T}{\log T}} \right).$$  \hfill (A-41)

Notice that, as $T \to \infty$, we have

$$\lambda_T \sqrt{\frac{T}{\log T}} \to \infty, \quad \sqrt{q_T} \frac{\lambda_T}{T} \to 0, \quad q_T \frac{\lambda_T}{T} \sqrt{\frac{\log T}{T}} \to 0, \quad \sqrt{\frac{\log T}{T}} \to 0.$$  \hfill (A-42)

where the first three conditions are assumed in Proposition 3 while the last one is trivial.

Finally, consider the complementary of (A-39), then, by combining (A-35)-(A-37) with (A-40), we have that for $T$ sufficiently large and for any $\eta' > 0$

$$\Pr \left( |A_{1Tj}| + |A_{2Tj}| + |A_{3Tj}| \geq K_4 \lambda_T \sqrt{\frac{T}{\log T}} \right) \leq \sum_{k=1}^{3} \Pr \left( |A_{kTj}| \geq K_4 \lambda_T \sqrt{\frac{T}{\log T}} \right) = O(T^{-\eta'}).$$

which implies that

$$\Pr \left( |S_Tj(\hat{\theta}^A_T, \hat{c}_T)| \leq \frac{\lambda_T}{\max_{j \in A^c} |\theta_{Tj}|} \right) \geq 1 - O(T^{-\eta'}).$$  \hfill (A-43)
Given \( n = O(T^\zeta) \), define \( \eta' = \eta + \zeta \), then for \( T \) sufficiently large and for any \( \eta > 0 \), from (A-41) we have

\[
\Pr \left( \max_{j \in \mathcal{A}} |S_{T,j}(\hat{\theta}_T^A, \hat{c}_T)| \geq \frac{\lambda_T}{\max_{j \in \mathcal{A}^c} |\theta_{T,j}|} \right) \leq n \Pr \left( |S_{T,j}(\hat{\theta}_T^A, \hat{c}_T)| \geq \frac{\lambda_T}{\max_{j \in \mathcal{A}^c} |\theta_{T,j}|} \right) = O(T^{-\eta}).
\]

By considering the complementary event we complete the proof. \( \square \)
